Those with symptoms or heart failure have a class I indication for pacemaker implantation (recommendation 1). Subtle symptoms may, however, be more challenging to identify, such as long naps and nightmares.²⁷¹ Further class I indications include a wide QRS escape rhythm, complex ventricular ectopy, or ventricular dysfunction (recommendation 4). The upper limit of normal for QRS duration varies with age.²⁶² By adult standards a wide complex in a newborn may be narrow; for example, between days 2 and 7 of age a QRS duration of 70 msec is above the upper limit of normal. Complex ventricular ectopy is not defined in the document but can be taken to mean ventricular couplets or more.

Congenital third-degree atrioventricular block in the infant with a ventricular rate less than 50 to 55 beats per minute or with congenital heart disease and a ventricular rate less than 70 beats per minute is a class I recommendation for permanent pacing. This recommendation does not specify an awake or asleep state, and the original studies

reporting these thresholds did not have 24-hour Holter data.^{272,273} However, this is frequently extrapolated to mean an average heart rate over 24 hours. Many paediatric centres would undertake anti-bradycardia pacing in any child with complex congenital heart disease and congenital complete atrioventricular block.²⁷¹

Recommendations for those with congenital complete heart block beyond the first year of life continue to use a heart rate of less than 50, but as a class IIa recommendation, leaving more room for interpretation by the physician. Of note is that in the original study, the heart rate of 50 which was used as a threshold was a mean daytime junctional rate.²⁷⁴ The second part of this recommendation: abrupt pauses in ventricular rate that are two or three times the basic cycle length refer to the possibility of junctional exit block with the implication of an unstable escape mechanism. Pauses of at least 3 seconds while awake or 5 seconds while sleeping have also been used as a criterion for anti-bradycardia pacing (Fig. 19-18).²⁷¹

Long-QT syndrome with 2:1 atrioventricular or third-degree atrioventricular block is a class IIa indication. Whether or not one considers the syndrome to be present a prolonged QTc in the setting of congenital complete atrioventricular block (Fig. 19-19) is widely considered an indication for anti-bradycardia pacing and is alluded to in the guidelines.^{41,270,271,275}

Those patients with significant bradycardia who do not undergo anti-bradycardia pacing require meticulous follow-up with serial electrocardiograms, Holter monitors, and echocardiograms. There is little data on echocardiographic monitoring; however, serial echocardiography is useful to document ventricular size and function as well as mitral valve regurgitation.²⁷¹ Ventricular dysfunction is now included in the class I recommendations, and dilatation and/or mitral regurgitation could be considered relative indications to pace.

Michaelsson has recommended that all patients with congenital complete atrioventricular block be paced by the time they reach adolescence because of a significant risk of syncope or sudden death at any time thereafter even in the absence of poor prognostic signs. This recommendation is covered in the guidelines by class IIb recommendation 2 and is becoming increasingly accepted.^{270,271,276}

2:1 Atrioventricular Block

Patients with 2:1 atrioventricular block require meticulous ongoing follow-up as block may progress and the nature and rate of the escape rhythm are unpredictable. Individual consideration using the criteria for complete atrioventricular block is often helpful. For example, symptoms, a wide QRS complex, a prolonged corrected QT interval, or

Figure 19-18 A significant pause, of 5.8 seconds, was recorded overnight in a 10-year-old patient with congenital complete heart block. The pause length is not a multiple of the previous RR interval, so it is not of the type referred to by class IIa, recommendation 2. The presence of multiple pauses like this, however, led to insertion of an anti-bradycardia pacemaker.

Figure 19-19 Complete heart block in a newborn. The atrial rate is 145 beats per minute, while the ventricular rate is only 50 beats per minute. The corrected QT interval is prolonged at 0.58 seconds. In addition, the QRS duration is prolonged for age at 105 msec. Both are independent indications for anti-bradycardia pacing. P, P-wave.

complex ventricular ectopy would be reasons to proceed with anti-bradycardia pacing.

Pacing for Post-operative Atrioventricular Block

Because of a high risk of sudden death, post-surgical advanced second- or third-degree atrioventricular block persisting or that is not expected to resolve or persists for at least 7 days after cardiac surgery is a class I indication for pacemaker implantation.²⁷⁷ Unless the surgeon is confident of extensive damage to the conduction system, it is important to wait at least 7 to 9 post-operative days, as recovery of conduction system function is common.

Patients in whom post-operative advanced second- or third-degree atrioventricular block has resolved and in whom conduction returns to normal have a good prognosis and pacing is not indicated (class III, recommendation 1).⁴⁰ If there is incomplete recovery with new residual bifascicular block (complete right bundle branch block and left-axis deviation) uncertainty remains and this is included in class IIb as recommendation 1. Long-term instability of the conduction system has been postulated in patients with even transient post-operative heart block, and is thought to contribute to late sudden death in some patients.²⁷⁸ Thus, these patients should be monitored for any recurrence of heart block or evidence of arrhythmia with regular Holter monitors.

Pacing for Bradycardia-Tachycardia Syndrome

Sinus bradycardia alternating with atrial fibrillation/flutter, intra-atrial re-entry tachycardia, or sinus node re-entry tachycardia is a common problem following surgery for congenital heart disease. Such patients warrant individual consideration of a management plan. Anti-bradycardia pacing with or without atrial anti-tachycardia pacing may be part of a management plan that includes antiarrhythmic medication. Other strategies may include catheter ablation or surgical revision with surgical creation of lines of block to prevent intra-atrial re-entry.^{48,159}

Pacing for Syncope and Breath-Holding Spells

In adult practise the use of pacing for patients with neurally mediated syncope may have a role for those who have minimal or no prodrome, those who fail standard therapy, or those who have profound bradycardia or asystole during syncope.²⁷⁹ For such patients, pacing may increase the time from the onset of symptoms to loss of consciousness, providing critical time for evasive action. The practise, however, is controversial with considerable evidence of a placebo effect.²⁸⁰ The use of pacing for this indication in paediatrics is rare. Pacing has been used with excellent results for the rare child with severe breath-holding spells associated with profound bradycardia and major pauses.²⁸¹

Pacing for Long QT Syndrome

Anti-bradycardia pacing with a moderately high baseline heart rate (usually a lower rate of 80–90) has been used as an adjunct to β -blocker therapy in long QT syndrome.²⁸² The rationale is that an increased heart rate shortens the QT together with the minimisation of pause-related QT prolongation. This use of pacing (which is not entirely

protective) has diminished somewhat since the advent of the implantable cardioverter defibrillator but continues to be used. Some patients (particularly neonates) with a very long QT may have functional 2:1 block and these patients may benefit from pacing; despite pacing, however, this presentation of long QT syndrome is associated with a high risk of sudden death. Long-QT syndrome with 2:1 atrioventricular or third-degree atrioventricular block is a class IIa indication for pacing. Proven pause-dependent initiation of ventricular tachyarrhythmias with or without a long QT is a class I indication. Pacing is also used in patients with long QT and sinus bradycardia, which may be caused or exacerbated by β -blockers. Some have advocated the use of special pacing algorithms in all long QT patients to virtually eliminate pauses, as torsades de pointes may be pause dependent.²⁸³ The use of implantable defibrillators in a subgroup of high-risk long QT patients is of proven benefit and is likely to be safer than pacing alone, despite the potential problem of a defibrillator shock causing an adrenaline surge, creating an electrical storm.²⁸⁴

Pacing for Hypertrophic Cardiomyopathy

Dual-chamber pacing can theoretically diminish left-ventricular outflow obstruction in hypertrophic cardiomyopathy by changing the activation sequence of the ventricular myocardium. When intrinsic atrioventricular conduction is intact, a short atrioventricular interval must be programmed to change the activation sequence. The response to pacing in hypertrophic cardiomyopathy is variable and it is not considered a first-line therapy. Randomised trials have failed to demonstrate benefit.²⁸⁵ This treatment does not prevent sudden death and the interest in isolated dual-chamber pacing for this condition has diminished over recent years in light of important data showing the efficacy of the implantable defibrillator in decreasing sudden death.

PACEMAKER FUNCTION

Pacemaker Modes

Pacing modes (Table 19-3) are now classified by a five-position code.²⁸⁶ This is often shortened to the first three positions. The first position describes the chamber(s) paced and the second the chamber(s) sensed. The third position describes the response to sensing. The fourth position indicates rate modulation, and the fifth position indicates multi-site pacing, if any.

For example, the code VVI indicates that the ventricle alone is paced and sensed and the response to sensing is to inhibit pacing. An R in position 4 would refer to the additional feature of rate response. Thus, VVIR is the same as VVI except that the rate of pacing can vary in response to in-built sensors in the device.

In DDD pacing, there is dual-chamber (atrium and ventricle) pacing and sensing and there is a dual response to sensing, depending what is sensed.²⁸⁷ Other complex modes of pacing such as DDI, DVI, and VDD are less commonly used, but can occasionally be helpful in patients with atypical electrophysiology or device problems such as impaired sensing.²⁸⁷

Understanding the underlying physiology is critical to choosing the optimal mode. For example, AAIR is an appropriate mode for sinus node dysfunction with intact atrioventricular node function and VDD or DDD an appropriate mode for atrioventricular block with normal sinus

TABLE 19-3

*Five position NASPE/BPEG code for description of pacing mode. This is often shortened to the first three positions. The first position describes the chamber(s) paced and the second the chamber(s) sensed. The third position describes the response to sensing. The fourth position indicates rate modulation, and the fifth position indicates multi-site pacing, if any. From Bernstein AD, Daubert JC, Fletcher RD, et al: The revised NASPE/BPEG generic code for antibradycardia, adaptive-rate, and multisite pacing. North American Society of Pacing and Electrophysiology/British Pacing and Electrophysiology Group. *Pacing Clin Electrophysiol* 2002;25:260–264.

node function. The physician must also be aware that the underlying physiology can evolve.

Pacemaker Timing Cycles and Programming

The multiple features of the current generation of pacemakers can create complex programming issues which need to be understood to interpret pacemaker electrocardiograms correctly. This is often critical in order to decide if there is any dysfunction of the pacemaker system or to allow optimisation of pacemaker settings. The task is often made easier by using diagnostic features built into the device that can provide labelling of events.

Pacemaker function is determined by a number of in-built timing cycles which are measured in milliseconds and often programmable. These include periods where sensing circuits are refractory (temporarily switch off their sensing function).²⁸⁷ Some basic concepts will be covered here. In single-chamber pacing, such as VVI or AAI, each sensed or paced event is followed by a refractory period to ensure that associated depolarisation and repolarisation is not sensed as an additional event by the device.

Dual-chamber pacemakers, as expected, have a greater number of programmable intervals. The atrioventricular interval begins with a sensed or paced atrial event and ends with a sensed or paced ventricular event. Setting the atrioventricular interval and lower rate limit determines the critically important atrial escape interval, during which an intrinsic atrial event is sought to commence the next cycle or, if no sensed event from either chamber occurs, an atrial paced event occurs at the appropriate time.

The post-ventricular atrial refractory period is present to prevent sensing of P waves which have conducted retrograde and/or far-field ventricular repolarisation on the atrial channel. The aim is to prevent pacemaker-mediated tachycardia, which may occur when a retrograde or far-field signal is sensed and tracked in the ventricle. Pacemaker-mediated tachycardia is a re-entrant rhythm, with one limb of the re-entrant loop being the patient's retrograde conduction, and the other the pacemaker.

Atrial sensing is refractory during the atrioventricular interval and together the atrioventricular interval and the post-ventricular atrial refractory period constitute the total atrial refractory period which can limit the upper atrial tracking rate of the pacemaker.

A detailed understanding of timing cycles and refractory periods is required by those who programme pacemakers in paediatric patients. The default out of the box settings

are based on typical adult patients, and are inappropriate for paediatric patients. Younger patients have higher heart rates than adults and attention needs to be given to the potential for pacemaker-mediated Wenckebach and even 2:1 paced atrioventricular block to occur at higher rates.

Special Features

A number of special features are available in the current generation of pacemakers and many of them are applicable to children.

Almost all pacemakers have the ability for rate-responsive (adaptive) pacing. In-built sensors are used to detect movement or physical activity and/or physiological parameters such as minute ventilation. The device can then respond to these indicators of increased physiological demand by increasing baseline heart rate. This feature is used for any loss of chronotropy, such as sinus node dysfunction or complete heart block with single-chamber ventricular pacing. It is available in either single- or dual-chamber devices, but is not appropriate until the child is able to walk. The sensitivity and responsiveness of the sensor can be adjusted to mimic normal physiology. In-built features such as heart rate graphs as well as assessment with Holter and exercise testing may be useful when optimising the settings for a patient, and some devices have automatic optimising algorithms.

Mode switching is an important feature of most dual-chamber pacemakers, designed to minimise ventricular tracking of an atrial tachycardia. For example, if a patient in DDD mode suddenly developed an intra-atrial re-entry tachycardia, the pacemaker would detect the high atrial rate and change the mode to DDIR; thus, the ventricular paced rate will be appropriate for the level of activity (sensor indicated rate) rather than inappropriately fast due to tracking of the atrial arrhythmia at the upper tracking rate (Fig. 19-20). Mode switching can add considerably to the complexity of interpreting pacemaker timing cycles, but it is essential in many patients with intermittent atrial tachycardias.²⁸⁸

Other safety and efficiency features have been developed and many have become automated. For example, some pacemakers have the ability to detect problems with the hardware, such as a significant increase in lead impedance (which could indicate a lead fracture). If such problems are detected, the device can automatically make changes to programming to ensure optimal function. Many new pacemakers have the ability to regularly check the pacing thresholds and adjust the outputs (with a programmable margin

Figure 19-20 Automatic mode switching. The top part of the tracing shows an electrocardiogram with event markers. The bottom part of the tracing shows simultaneous atrial electrogram demonstrating atrial tachycardia. Each square represents 200 milliseconds. In the early part of the tracing, only every second atrial depolarisation is sensed. The other atrial depolarisation is not recognised, as it lies within the post-ventricular blanking period. An in-built algorithm intermittently seeks this situation. When the device recognises the underlying atrial tachycardia, mode switching occurs, and the paced rate slows to the sensor indicated rate. AR, atrial sensing falling within refractory period; AS, atrial sense; MS, mode switch; VP, ventricular pace.

of safety) to minimise battery usage. Such a setting would not be appropriate for children with long QT syndrome as a pause could potentially be caused (a known risk factor for torsades de pointes in some long QT patients). This feature has been designed to work with endocardial leads but it has been shown it can work successfully in children who have epicardial leads.²⁸⁹ Prior to using this feature it should be tested for a period in the monitor only mode to ensure it functions well and safely in an individual child.

IMPLANTATION CONSIDERATIONS

Pacing in paediatric cardiology and congenital heart disease presents a unique set of challenges. Small patient size, patient growth, intracardiac shunts, complex anatomy, long-term venous access, surgical scarring, abnormal myocardial performance, and late post-operative arrhythmias are but a few of the issues that frequently arise in the care of this population. A good understanding of the basic principles of pacing allows individualised decisions to be made for each patient's circumstances.

Epicardial Versus Endocardial Implantation

Pacing leads are generally considered the most vulnerable and unreliable part of any pacemaker system and the majority of pacemaker system problems are directly related to lead issues. This is especially the case in paediatrics and congenital heart disease.²⁹⁰ Given a likely life-long need for pacing, long-term vascular access is a critical issue. Endocardial leads in younger patients carry the risk of venous obstruction or thrombosis, making placing future pacemaker systems increasingly difficult. In the neonate and infant, most centres use an epicardial approach when pacing is needed, although controversy remains as to what the cut-off for endocardial pacing should be.

Most epicardial pacing is now performed using steroid-eluting leads which minimise inflammation at the lead-myocardial interface and have significantly better performance than the previous generation of epicardial screw-in leads. The performance of the newer leads is now competitive with endocardial leads.^{291,292}

Pericardial effusion and post-pericardiotomy syndrome can occur after epicardial pacemaker implantation and also rarely after endocardial implantation, and must be considered if a patient is displaying symptoms consistent with post-pericardiotomy syndrome.²⁹³

Predictors for venous obstruction in children have been sought, and in one retrospective study a predictive index was created to evaluate the risk of venous obstruction.²⁹⁴ In this study, the sum of the cross sectional area of all leads was indexed to body surface area at implant, a result greater than 6.6 mm²/m² predicted venous obstruction with a sensitivity of 90% and a specificity of 84%. This index has been used to help determine who should receive an epicardial versus a transvenous system. However, subsequent studies have had conflicting results and the issue remains controversial.^{295,296}

Each centre, depending on policy and experience has different cut-offs for deciding who should receive an epicardial versus a transvenous system. When considering using endocardial pacing in the younger child, one must take into account the child's size and anatomy, as well as the body habitus of the child.²⁹⁴ Although transvenous pacing has been shown to be possible in infants, it should be avoided if possible because of the risks of pocket erosion, venous obstruction, as well as growth-related problems such as tension on the lead. The goals of pacemaker implantation must address both adequacy of pacing and long-term issues such as venous patency and potential need for future lead extractions.^{297,298}

Traditionally endocardial ventricular pacing leads were placed into the right ventricular apex for stability and ease of placement. However, mounting evidence regarding the potential creation of myocardial dysfunction through ventricular dyssynchrony has led many away from this practise, and many leads are now placed on the ventricular septum.²⁹⁹

Unipolar Versus Bipolar Leads

In bipolar pacing systems the lead tip is the cathode (the negative electrode) and the closely adjacent lead ring (or in the case of epicardial electrodes a second lead button) is the anode (the positive electrode, or ground). Unipolar pacing systems use the lead tip as the cathode and the pacemaker box as the anode (ground). Sensing occurs via these same circuits. Unipolar leads have the potential disadvantage of an increased possibility of oversensing of non-cardiac signals and of unwanted skeletal muscle stimulation. Many centres prefer to use bipolar systems (due to frequently better sensing performance); however, when lead dysfunction occurs it is possible, in most devices, to reprogramme sensing, pacing, or both, to either unipolar or bipolar mode. In epicardial systems, not infrequently when bipolar pacing or sensing is inadequate, a change to unipolar will allow

satisfactory pacemaker settings. This would usually occur when the lead damage has occurred in the pole that is switched off with the change for bipolar to unipolar.

Congenital Heart Diseases

Most authorities would agree that patients with intra-cardiac shunts should have epicardial devices. This is because patients with transvenous leads and an intra-cardiac shunt have a greater than two-fold risk of a systemic embolic event than those with epicardial leads.³⁰⁰ Even patients with minimal, apparently pure left-to-right shunts may be at risk of embolism due to the possibility of a potentially altered haemodynamic sequence after pacing creating a brief period of right-to-left shunting.³⁰¹

There is controversy regarding the placement of atrial pacing leads in Fontan anatomy. Some centres find the placement of endocardial atrial leads acceptable in patients without shunts, while other centres avoid placing endocardial leads within a Fontan circuit because of the potential for pulmonary emboli or systemic emboli in patients who have a fenestration. Unfortunately many patients who have had a Fontan operation have significant scarring and it can be difficult to obtain appropriate sensing and capture thresholds. When scarring precludes any possibility of appropriate pacemaker function from a traditional epicardial approach, surgically placing the lead transmurally with only its tip extending into the cardiac chamber may prove useful.³⁰²

Pacemaker Infection

An important potential complication of device insertion is system infection. Most centres routinely prescribe prophylactic peri-operative antibiotics. System revision and the presence of trisomy 21 have been shown to be risk factors for infection in paediatric patients.³⁰³ Management of deep pocket infection should involve removal of the device and the leads in their entirety. The recently published American Heart Association guidelines for prevention of endocarditis do not recommend prophylaxis for patients with endocardial pacing leads.³⁰⁴

Dual-Versus Single-Chamber Pacing

In adults with structurally normal hearts the choice between single- and dual-chambered devices under various circumstances has provided the substance for much debate over the years.³⁰⁵ In the adult community debate continues and practise varies widely despite a large amount of data. Although maintaining atrioventricular synchrony is intuitively appealing, there is evidence to support greater importance of minimisation of ventricular pacing.³⁰⁶ In paediatrics and congenital heart disease individual consideration is made in each patient. Frequently younger, smaller children have a smaller single-chamber system as their first device, which at a future time is upgraded to a dual-chamber system when a system revision is required.

Patients with impaired haemodynamics may particularly benefit from having atrioventricular synchrony, so frequently have dual-chamber devices prescribed early in life. Some new generation devices have the capability of compound modes that give preference to intrinsic

atrioventricular conduction to minimise ventricular pacing, while allowing for back-up ventricular pacing in the event of intermittent atrioventricular block.

Pacemaker Syndrome

Pacemaker syndrome comprises a constellation of symptoms resulting from loss of atrioventricular synchrony or retrograde ventriculoatrial conduction, and can occur in children.³⁰⁷ When there is lack of sequential or physiological atrioventricular filling due to atrial contraction against closed atrioventricular valves during ventricular systole, transient increases in atrial pressure are caused. This may lead to symptoms including fatigue, exercise intolerance, a sensation of fullness, dyspnoea, and headache. It may also provoke vagal mediated changes associated with dizziness and syncope.³⁰⁸ The syndrome most frequently occurs in patients with single-chamber ventricular pacing systems, but can also be seen with dual-chamber systems with inappropriate atrioventricular delay settings. It is less common in children than adults but may develop over time.³⁰⁷ Treatment can include adjustment of atrioventricular intervals (including rate adaptive features) for those with dual-chamber systems and upgrading those with single-chamber devices to a dual-chamber system.

PACEMAKER FOLLOW-UP

All patients with any implanted rhythm devices require long-term follow-up. Monitoring for any evidence of change in device or patient status is essential, so that appropriate programming or hardware revisions can be made when necessary.

After interrogation the programmer can display important information including device warnings, estimated remaining battery life, lead impedances, and information about percentage of sensing/pacing and any tachyarrhythmias detected (sometimes including annotated electrograms of the rhythm). Heart rate graphs are commonly available. Often the type of information available is programmable.

A sudden rise in lead impedance should arouse suspicion of a lead fracture. Similarly a fall in lead impedance may represent an insulation break.

If possible the nature and rate of the underlying rhythm should be documented, by slowly reducing the pacing rate, until intrinsic rhythm emerges. If the patient displays any symptoms, the testing for intrinsic rhythm should be terminated. Most devices do not allow the rate to be turned down to less than 30 and if there is no underlying ventricular rhythm coming through the patient is classified as pacemaker dependent. Tolerable levels of short-term bradycardia vary among patients, and attention should be paid to the comfort level of the patient. It is important that pacing never be abruptly ceased, as suppression of the intrinsic rhythm is likely to be seen at physiologic pacing rates, and thus unacceptably long pauses might be seen.

Regular meticulous follow-up is mandatory to ensure that the pacemaker system is safe and set optimally and battery life is maximised. Each brand of device has its own proprietary programmer. The timing of follow-up depends on the complexity and stability of the patient and the system. Typically devices are checked the day after

implantation, in 2 to 4 weeks, 3 months, and 6 months. The frequency of long-term follow-up is determined by a variety of factors related to both the device and the child. Those with pacemaker dependency, cardiac resynchronisation devices, and implantable defibrillators require more frequent follow-up.

Testing Sensing

Pacemakers are nearly always programmed to sense or to detect spontaneous cardiac depolarisations. Appropriate sensing is critical for acceptable device function. The sensing setting is the amplitude in millivolts that the device has to perceive in order that it acknowledges the presence of an intrinsic beat. Typically the device is then set with at least a two times sensing margin of safety. As an example, imagine a patient with complete heart block and a stable junctional escape rate of 55 beats per minute. For testing ventricular sensing, the ventricular rate is slowly decreased to below the rate of the intrinsic rhythm, so no pacing should occur. The ventricular sensing is set at a low level (for example, 2.0 millivolts), and then increased incrementally until appropriate sensing of the intrinsic rhythm is lost and pacing occurs. The last level at which appropriate sensing was seen is the sensing threshold.

Intrinsic atrial signals usually have a lower amplitude than ventricular signals as they are created by a smaller muscle bulk. Thus, to adequately identify the amplitude of intrinsic atrial signals one must start at very low levels, such as 0.5 millivolts.

Oversensing should also be tested for, and is most commonly seen in unipolar systems. Isometric manoeuvres involving the muscles close to the implantation site are performed during paced rhythm. If oversensing occurs, muscle noise will be picked up inappropriately as noise and pacing will not occur.

Testing Threshold

The threshold is the minimum electrical stimulus required to consistently capture the heart and trigger contraction. The stimulation threshold is a square wave, a function of both amplitude (measured in volts) and pulse width (measured in milliseconds). The threshold is tested by keeping the amplitude stable and decreasing the pulse width (or vice versa) until capture no longer occurs. In Figure 19-21 ventricular capture is demonstrated by a ventricular pacing artefact followed immediately by a wide

QRS complex with a T wave in the opposite direction of depolarisation. Atrial capture is demonstrated by P wave immediately preceded by an atrial pacemaker artefact. It is important to remember that bipolar systems may not show any pacing spikes on a surface electrocardiogram, and thus electrogram morphology of the P wave and QRS must be relied upon to indicate capture of the paced chamber. Obviously when testing threshold the testing rate needs to be faster than the underlying rate (unless pacing in an asynchronous mode), or pacing will not occur. In complete heart block, atrial threshold is usually tested in DDD mode. Output should then be set at three times the pulse width or twice the amplitude to ensure an adequate safety margin, given the inherent variability of cardiac thresholds.

Many paediatric centres routinely programme pulse width with a three times pulse width threshold margin of safety in standard patients. Increasing voltage amplitude comes at a high price for battery life. The hyperbolic strength-duration curve describes the relationship between pulse duration and voltage at threshold (Fig. 19-22). At short pulse durations, an increase in pulse duration significantly lessens the voltage required but at longer pulse widths, there is little decrease in voltage for the same increment in pulse width. This must always be considered when programming. In some cases it helps to construct a strength-duration curve to optimise output settings. Some devices have testing algorithms that allow easy construction of a curve.

Pacemaker Clinic Routines

For patients with endocardial leads a regular (usually annual) chest X-ray throughout childhood is typically performed to look at lead position and the effects of growth. Some centres are decreasing the frequency of routine chest X-rays due to concerns over radiation exposure, and only performing them if there are clinical concerns or if there has been an impressive growth spurt. A regular chest X-ray for those with epicardial leads is appropriate to look for the rare but important complication of cardiac strangulation.³⁰⁹ Although this has only been rarely reported, it can be fatal. Strangulation can still occur after a lead has been abandoned.

An annual Holter monitor is useful to check pacemaker function over a 24-hour period and screen for the emergence of and interaction with any tachyarrhythmias. Sometimes premature ventricular contractions are not sensed as well as intrinsic ventricular rhythm. Unless this

Figure 19-21 Ventricular threshold test. In this example, the amplitude is kept stable at 2.0 V and the pulse width is progressively decreased. Capture is demonstrated by a ventricular pacing artefact followed immediately by a wide QRS complex with a T wave in the opposite direction of depolarisation. At 0.12 msec, each pacemaker artefact is followed by a captured beat. At 0.09 msec, only the first beat is captured. Two further pacing artefacts are not followed by ventricular depolarisation, and later there is a ventricular escape beat. The threshold is described as 0.12 msec at 2.0 V. VP, ventricular pace.

Figure 19-22 The hyperbolic strength-duration curve. This curve was estimated by a device algorithm after threshold testing. Each point on the curve describes the amplitude in volts and the pulse duration in milliseconds of various thresholds. At short pulse durations an increase in pulse duration significantly lessens the voltage required but at longer pulse widths, there is little decrease in voltage for the same increment in pulse width. This must always be considered when programming.

Figure 19-23 Differential sensing of premature ventricular contractions. The top panel shows the surface electrocardiogram, while the middle panel shows marker channels. The bottom panel shows an endocardial electrogram on a scale of 2 millivolts per millimeter. The middle beat is an atrial-paced event followed by a premature ventricular contraction. The amplitude of the sensed signal from the premature ventricular contraction is significantly smaller than the conducted ventricular beats. At some sensing settings, this could result in the undersensing of premature contractions. AP, atrial paced event; VS, ventricular sensed event.

is seen at a pacemaker check (Fig. 19-23), the only way to diagnose this is on Holter. There is a potential risk of ventricular arrhythmias if premature ventricular contractions are undersensed, as pacing may occur at a critical time and initiate a ventricular arrhythmia.

An annual echocardiogram is important to check ventricular function and any mechanical lead effect on valvar function (particularly tricuspid). Patients with bi-ventricular devices should have optimisation of the V-V and A-V interval under echocardiographic guidance to optimise ventricular function.

Keeping database information for all pacemaker patients is important, as from time to time there are device advisories or recalls necessitating contact and review of all patients with a particular lead or device.

Pacemaker Dependence

Patients with no underlying rhythm may collapse or die if their pacemaker loses ventricular capture. In this situation some centres set the device with broader safety margins than usual, but there is no clear data available to guide this practise. Individual decisions should be made based on apparent risk of threshold change versus cost to battery longevity. Successful use of a pacemaker with an integrated home monitoring facility that can send a message to a mobile phone-like receiver if there is a significant threshold rise has been reported in a child with no underlying rhythm.³¹⁰ Regular meticulous follow-up at more frequent intervals is appropriate.

Restrictions for Patients with Implanted Devices

All paediatric cardiologists need to encourage their patients to lead a healthy, active lifestyle. Some sporting activities with a high risk of bodily impact have the potential to damage the pacemaker system and cannot be recommended in patients who are pacemaker dependent. Depending on the underlying heart disease, the underlying rhythm, and the potential for tachyarrhythmias individual decisions need to be made regarding prescription/restriction of activity in other patients. Doctors make recommendations and then families make informed medical decisions. With respect to athletic activity restrictions, many teenagers and their families may not take heed of our advice!

Non-cardiac Surgery and Magnetic Resonance Imaging

Patients undergoing non-cardiac surgery need to have a plan made in advance about intra-operative pacing. Problems that can be encountered include diathermy signals being falsely sensed as myocardial signals resulting in inhibition of pacing. Bipolar diathermy is preferred, but still may cause some electrical interference. In some cases it is safer to change the device to a non-sensing mode (VOO or DOO) for the duration of the surgery. Electrocardiographic monitoring during the surgery is of course mandatory.³¹¹ If no intra-operative changes are made, a pacemaker check after surgery is sensible to make sure there has been no electrical or hardware damage to the device.

In general, performing magnetic resonance imaging in patients with an implanted device is contraindicated. Death has been reported in pacemaker patients. There are a variety of mechanisms by which MR can affect pacemakers and implantable cardioverter defibrillators (ICDs). Potential interactions can involve multiple components of the device, including the leads, circuitry, reed switch, battery, and capacitors. There is now controversy about whether contraindications are absolute or relative. Device manufacturers are seeking ways to make devices magnetic resonance imaging safe.³¹²

Temporary Pacemakers

Temporary pacemakers are an integral part of post-operative management following surgery for congenital heart disease. Indications for pacemaker use in these circumstances are usually

- To treat bradyarrhythmia, such as complete heart block, sinus bradycardia

- To achieve atrioventricular synchrony in the treatment of junctional ectopic tachycardia, as an adjunct to cooling and/or antiarrhythmic medication
- To overdrive re-entry tachyarrhythmias
- To use pacing manoeuvres to diagnose an arrhythmia mechanism

Sensing and pacing thresholds should be tested at least daily in any actively used temporary pacing wires, as temporary wire thresholds shift rapidly and unpredictably. With older generation pacemakers, patients with complete heart block may be at risk of losing pacing because of cross-talk. The atrial output pacemaker artefact is falsely sensed by the ventricular lead as ventricular activity and therefore no ventricular pacing ensues. Newer generation temporary pacemakers have a cross-talk sensing window to avoid this problem. All patients having temporary pacing should in addition to electrocardiogram monitoring have some form of physiological monitoring as pacing spikes without capture can be interpreted by electrocardiogram monitoring systems as a rhythm.

Future Directions for Bradycardia Pacing

A novel leadless pacemaker system is under development and has been successfully tested in animals.³¹³ The system comprises an ultrasound transmitter delivering energy from the chest wall to a receiver-electrode in contact with the myocardium that then converts the ultrasound energy to electrical energy sufficient to pace. If the promise of the system is fulfilled, it will revolutionise pacing and be of tremendous benefit to paediatric patients. Considerable effort, using molecular biological techniques, is also being put into the development of a biological pacemaker but many obstacles remain.³¹⁴

IMPLANTABLE CARDIOVERTER-DEFIBRILLATORS

Ventricular arrhythmias can be seen in multiple paediatric and congenital heart disease populations, and sudden death can result from the most malignant and haemodynamically unstable of these rhythms. Implantable cardioverter-defibrillators have been shown to be effective in preventing sudden death due to arrhythmia in children and young adults with congenital heart disease or electrical myopathies.²⁸ There are a variety of diagnoses that may increase the likelihood of ventricular arrhythmias, including repaired congenital cardiac disease, primary electrical disease, such as the long QT syndrome, catecholaminergic ventricular tachycardia, and idiopathic ventricular fibrillation, as well as hypertrophic and dilated cardiomyopathies.^{315,316} There is consensus regarding indications of use of implantable defibrillators for secondary prevention, including patients resuscitated from cardiac arrest with documented ventricular arrhythmia, and documented haemodynamically significant ventricular tachycardia requiring cardioversion or defibrillation. Other indications that may fall into this category are those that are highly suggestive of ventricular tachycardias such as unexplained syncope in the setting of repaired congenital heart disease, and repeated syncope despite adequate treatment of primary electrical disease. Primary prevention, or defibrillators placed for high-risk clinical scenarios without documentation

of malignant arrhythmias, remain more difficult clinical decisions. Congenital heart disease with inducible sustained ventricular tachycardia at ventricular stimulation testing remains a controversial indication for implantable cardioverter defibrillators, although recent evidence suggests it may be clinically useful.²⁹ There are no paediatric randomised clinical trials looking at survival, and thus consideration of implantation of a cardioverter-defibrillator in this population must be guided by clinical judgement and extrapolation from the adult experience.

The American Heart Association and Heart Rhythm Society guidelines for cardioverter defibrillator implantation are based on adult studies, and thus do not always apply directly to the paediatric population, but can be a reasonable starting point⁴¹ (Table 19-4).

Several retrospective studies have demonstrated a high incidence of appropriate defibrillation therapies in children, but unfortunately inappropriate shocks are common as well.^{315,316} Inappropriate therapies frequently are due to supraventricular tachycardia with rapid conduction to the ventricle, sinus tachycardia, or lead failure.^{315–317} Most inappropriate therapies due to supraventricular tachycardia can be prevented by programming changes such as increasing the detection threshold and discrimination algorithms, as well as usage of β -blockers. It may sometime be helpful to determine the upper intrinsic rate with exercise testing, to ensure that sinus tachycardia does not exceed the ventricular fibrillation detection threshold.³¹⁷ However, these manoeuvres do not help with the inappropriate shocks that may occur due to lead failure, which is particularly high in the paediatric population.³¹⁵ Failed high-voltage leads frequently require extraction before a new lead can be placed, due to concerns of false sensing due to interaction of two ventricular leads. Cooper et al examined laser lead extraction in the paediatric and congenital heart disease population, and found that it could be safely and effectively performed with similar complication rates to that of the general population.²⁹⁸

When cardioverter-defibrillators were first used clinically, routine defibrillation threshold testing was performed. As the technology has advanced, and technical self-diagnostics have improved, there has been a move away from routine testing. One study in the paediatric and congenital population found that the majority of routine defibrillation threshold testing did not trigger any clinical changes. However, in patients in whom there was a clinical concern (such as change on X-ray, inappropriate shocks, or a change in pace/sense values), threshold testing revealed abnormalities that led to important programming or hardware modifications.³¹⁸ Thus, routine defibrillation threshold testing may not be necessary, but any important clinical changes should lead to consideration of repeated testing.

In patients with congenitally malformed hearts, implantation of cardioverter-defibrillators may be limited due to cardiac anatomy or patient size. Epicardial patches may be used in some of these patients, but require a thoracotomy and may lead to a restrictive pericardial process. Recently, alternative configurations have been used to allow implantation in patients who are too small for traditional transvenous implantation, or those with intracardiac shunting. These alternative configurations were first published in 2001, when three centres described cases where epicardial ventricular sensing leads were utilised

with a subcutaneously implanted high voltage coil, and the active generator was placed in an abdominal position.^{319–321} Another configuration used a transvenous high voltage lead placed in an epicardial position, also with an abdominally positioned active generator. Both of these alternative configurations have been used successfully in children and young adults with congenital heart disease, but the patients require close monitoring and follow-up, including routine testing of the defibrillation threshold, as they are new technologies and thus are prone to unanticipated complications.³²²

CARDIAC RESYNCHRONISATION THERAPY

Cardiomyopathy affects a variety of paediatric patients, including those with idiopathic dilated cardiomyopathies, congenital heart disease, and inherited cardiomyopathies. The failing heart often has an associated intraventricular conduction delay, which may be seen as a prolonged QRS or bundle branch block. This delay may correlate with dyssynchronous, inefficient contraction of the ventricles.

Using resynchronisation therapy, at least two regions of the ventricles are paced in an attempt to improve ventricular synchrony, and thus improve cardiac output. Resynchronisation therapy in adults with dilated cardiomyopathy and left bundle branch block has been shown to improve quality of life, increase exercise tolerance, and improve overall survival.^{323–325} The paediatric experience with resynchronisation therapy began primarily with the congenital cardiac disease population as well as dilated cardiomyopathy. These populations, however, are very different from the population of adults in whom resynchronisation therapy was initially utilised. The vast majority of the adult patients in early trials of resynchronisation therapy had ischaemic cardiomyopathy and left bundle branch block, although more recent trials have shown similar results with non-ischaemic cardiomyopathy patients.³²⁵ Patients with repaired congenital cardiac disease frequently have right bundle branch block, while left bundle branch block is relatively rare. The anatomy of patients with congenital heart disease is highly varied, and the regions of dyssynchrony vary similarly. Right ventricular failure, rather than

TABLE 19-4

AHA/ACC/NASPE RECOMMENDATIONS FOR ICD THERAPY

Class I (there is evidence and general agreement that placement of an implantable cardioverter defibrillator is appropriate)

1. Cardiac arrest due to VF or VT not due to a transient or reversible cause
2. Spontaneous sustained VT in association with structural heart disease
3. Syncope of undetermined origin with clinically relevant, hemodynamically significant sustained VT or VF induced at electrophysiologic study when drug therapy is ineffective, not tolerated, or not preferred
4. Nonsustained VT in patients with coronary disease, prior MI, LV dysfunction, and inducible VF, or sustained VT at electrophysiologic study that is not suppressible by a class I antiarrhythmic drug
5. Spontaneous sustained VT in patients without structural heart disease and not amenable to other treatments.

Class II (there is conflicting evidence or diverging opinion)

Class IIa (the weight of evidence favors placement)

1. Patients with left ventricular ejection fraction of less than or equal to 30% at least 1 month post-MI and 3 months post-coronary artery revascularization surgery

Class IIb (evidence is less well established)

1. Cardiac arrest presumed to be due to VF when electrophysiologic testing is precluded by other medical conditions
2. Severe symptoms (e.g., syncope) attributable to ventricular tachyarrhythmias in patients awaiting cardiac transplantation
3. Familial or inherited conditions with a high risk for life-threatening ventricular tachyarrhythmias such as long-QT syndrome or hypertrophic cardiomyopathy
4. Nonsustained VT with coronary artery disease, prior MI, LV dysfunction, and inducible sustained VT or VF at electrophysiologic study
5. Recurrent syncope of undetermined origin in the presence of ventricular dysfunction and inducible ventricular arrhythmias at electrophysiologic study when other causes of syncope have been excluded
6. Syncope of unexplained origin or family history of unexplained sudden cardiac death in association with typical or atypical right bundle-branch block and ST segment elevations (Brugada syndrome)
7. Syncope in patients with advanced structural heart disease in whom thorough invasive and noninvasive investigations have failed to define a cause

Class III (generally agreed that placement is not indicated)

1. Syncope of undetermined cause in a patient without inducible ventricular tachyarrhythmias and without structural heart disease
2. Incessant VT or VF
3. VF or VT resulting from arrhythmias amenable to surgical or catheter ablation; e.g., atrial arrhythmias associated with the Wolff–Parkinson–White syndrome, right ventricular outflow tract VT, idiopathic left ventricular tachycardia, or fascicular VT
4. Ventricular tachyarrhythmias due to a transient or reversible disorder (e.g., acute MI, electrolyte imbalance, drugs, or trauma) when correction of the disorder is considered feasible and likely to substantially reduce the risk of recurrent arrhythmia
5. Significant psychiatric illnesses that may be aggravated by device implantation or may preclude systematic follow-up
6. Terminal illnesses with projected life expectancy less than 6 months
7. Patients with coronary artery disease with LV dysfunction and prolonged QRS duration in the absence of spontaneous or inducible sustained or nonsustained VT who are undergoing coronary bypass surgery
8. NYHA class IV drug-refractory congestive heart failure in patients who are not candidates for cardiac transplantation

LV, left ventricular; MI, myocardial infarction; VF, ventricular fibrillation; VT, ventricular tachyarrhythmia.

From Gregoratos G, Abrams J, Epstein AE, et al: ACC/AHA/NASPE 2002 guideline update for implantation of cardiac pacemakers and antiarrhythmia devices: Summary article—A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (ACC/AHA/NASPE Committee to Update the 1998 Pacemaker Guidelines). *Circulation* 2002;106:2145–2161.

left, is most common, and a failing single ventricle can be of either right or left morphology. Dyssynchrony may be present with a normal QRS duration and these patients can still benefit from resynchronisation therapy.

The first studies of resynchronisation therapy in the paediatric and congenital population examined the response of patients immediately following repair of congenital heart disease.^{326,327} During repair, temporary epicardial pacing leads were placed allowing pacing at multiple ventricular locations. It was found that resynchronisation therapy could increase cardiac output, could increase systolic blood pressure, and in one study could assist in weaning from bypass.^{326,327} In patients with right bundle branch block, right ventricular pacing alone has also been used to resynchronise the heart.³²⁸ In one catheterisation-based study, pacing in right ventricle was found to increase cardiac index and dP/dt.³²⁹

Recently, as cardiac resynchronisation therapy has been used more in paediatric and congenital heart disease patients, more literature (predominantly in the form of case reports and series) has begun to emerge. Consistently it has been found that some (but not all) in this population can benefit from this form of therapy, and predictors of response have not yet been well identified.^{330–333} This difficulty has also been found in the adult population, and there is a tremendous amount of work looking now at identification of cardiac resynchronisation candidates. The largest of the paediatric studies of cardiac resynchronisation was published by Dubin and colleagues.³³⁴ The population consisted of 103 patients from 22 centres, with a median age at the start of resynchronisation of 12.8 years and a median follow-up of 4 months. The patients predominantly had repaired congenital heart disease, with a smaller portion having cardiomyopathy. Overall the majority of the patients had decrease in their QRS duration and increase in their ejection fraction. However, 11 patients did not appear to respond, and no clear unifying characteristics of those patients could be identified, perhaps in part due to the small numbers.

ANTI-TACHYCARDIA PACING

Patients with repaired congenital heart disease have a high incidence of tachycardias, particularly intra-atrial re-entrant tachycardias. Cardioversion must sometimes be used to return these patients to sinus rhythm, but others may benefit from automated anti-tachycardia pacemakers that can pace-terminate a re-entrant rhythm. These pacemakers employ burst pacing algorithms to interrupt re-entrant tachycardias, in both the atrium and the ventricle. The current generation of implantable defibrillators have anti-tachycardia pacing capacity, and have been found to be safe and effective (and thus reduce the number of shocks) for termination of some ventricular tachycardias in the population of adults with coronary arterial disease.^{335,336} Little data is available for ventricular anti-tachycardia pacing in children, but consideration should always be given to this therapy, given the possibility of reducing the incidence of shocks in this psychologically vulnerable group.³³⁷

Atrial arrhythmias are a frequent source of morbidity and even mortality in the population of patients with congenitally malformed hearts.^{338–341} Atrial anti-tachycardia pacing has been studied in this population, and has been shown to be safe and effective in more than half of

the population.³⁴² Due to younger, healthy atrioventricular nodes and thus frequent one-to-one atrioventricular conduction in this population, some episodes of atrial flutter were misclassified by the device as ventricular tachycardias, and thus not treated with atrial anti-tachycardia pacing. To optimise the efficacy of these systems, consideration should be given to treatment with an atrioventricular nodal blocking agent, to minimise the incidence of one-to-one conduction. Although only half of the episodes of intra-atrial re-entrant tachycardia were successfully detected and treated, these episodes could have represented multiple cardioversions for these patients, and thus even partial efficacy may offer significant improvement in quality of life.

SUMMARY

The majority of electrophysiological studies in children are currently performed with a view to proceed to radio-frequency ablation of arrhythmias. Ablation has a high rate of success, has a low incidence of complications, and is cost effective. It can now be offered as first-line treatment to children of school age when the parents or child prefer this option to medication, or when medication is not tolerated. Acceptable alternatives to ablation include observation only with no treatment (for infrequent and easily controlled tachycardias) or treatment with medication. In younger children, who may spontaneously outgrow the arrhythmic substrate and in whom the complication rate may be higher, ablation is usually restricted to life-threatening arrhythmias, to those in whom medication cannot control the arrhythmia, where medication causes severe side effects, or in advance of proposed cardiac surgery. With the continued development of equipment and advances in techniques, it is likely that the rates of success will continue to increase and more arrhythmic substrates will become amenable to curative catheter ablation.

Pacemakers and implantable defibrillators have dramatically decreased in size and increased in sophistication and programmability, allowing for much broader indications and application in the paediatric and congenital heart disease population. As survival continues to improve following congenital heart disease repair, and better understanding is gained of the risk factors for sudden death, usage of these devices will only grow in the management of children with cardiac disease.

ACKNOWLEDGEMENTS

We would like to thank our teachers, mentors and colleagues, particularly those at Boston Children's Hospital, The Hospital for Sick Children in Toronto, and The Royal Children's Hospital, Melbourne, as well as Dr. Eric Rosenthal, who wrote the previous edition of this chapter.

This lovely review article from Texas Children's Hospital covers the topic of congenital complete atrioventricular block in great depth and gives an excellent perspective. It is essential reading for all paediatric cardiology trainees.

Cardiopulmonary Stress Testing

PAUL STEPHENS, Jr, MICHAEL G. MCBRIDE, and STEPHEN M. PARIDON

Regular exercise is an important part of a healthy lifestyle. Physical activity in some westernised societies has diminished for a variety of reasons as society has trended away from outdoor activities towards other types of activities, including computer games and cable television. Healthy levels of physical fitness require regular participation in activities that generate energy expenditures significantly above the resting level.¹

Exercise testing has become an integral part of the evaluation of children with congenital and acquired cardiovascular disease. Although children are seldom sitting or lying quietly during waking hours, most of the testing available to the cardiovascular specialist is performed in such a resting state, and sometimes in a sedated state. The evaluation of the patient in the exercise physiology laboratory allows the clinician to assess the cardiovascular system in a state that is more likely to be reflective of the normal daily physical activities.

Optimal exercise performance requires a continuous meshing of multiple systems of organs.² The roles of the heart and lungs are to provide adequate energy substrates to working skeletal muscle, and to remove the end products of aerobic and anaerobic metabolism during exercise. Most of the children that we encounter in the exercise physiology laboratory have, or are suspected of having, cardiac anomalies. Abnormalities of non-cardiovascular origin, however, may also play a role in limiting exercise performance in patients with surgically repaired complex congenital cardiac defects. Any malfunctioning of the muscles, bones, or nervous system will impair exercise performance. A modern laboratory for exercise physiology, therefore, must be capable of assessing all exercise-related systems, including the cardiovascular, pulmonary, neurologic, and musculoskeletal systems. Furthermore, accurate interpretation of exercise tests requires the proper equipment and personnel. This is particularly important as the cardiologist supervising the laboratory frequently evaluates children with real or suspected exercise limitations. These children seldom have any cardiovascular abnormalities, but may have involvement of other organs, such as dysfunction of the pulmonary or musculoskeletal systems. Properly performed exercise testing, and its interpretation, should also be able to identify or exclude abnormalities of extracardiac organs that normally contribute to exercise performance.

In this chapter, we review briefly basic exercise physiology as it relates to cardiopulmonary exercise testing. We discuss the equipment required for performing an exercise test, and its applications, assessing the types of data obtained from exercise testing, and their usefulness in the

evaluation of the child with cardiovascular disease. We also review indications and contraindications for exercise testing in cardiovascular disease.

BASIC EXERCISE PHYSIOLOGY

Assuring proper exercise performance requires the seamless and continuous meshing of multiple systems of organs.^{3,4} The classic illustration of Wasserman and colleagues (Fig. 20-1) is the widely duplicated figure that depicts the interaction of the key systems that couple internal cellular respiration to external pulmonary respiration during exercise. It shows the systems as a series of overlapping cogs, all of which must mesh seamlessly to allow exercise to occur. In such fashion, mechanical energy is produced from chemical energy at the cellular level, with subsequent delivery and removal of substrates for energy production and byproducts of muscle metabolism. All of this is accomplished while maintaining chemical and thermal homeostasis within narrow ranges.

CELLULAR METABOLISM

Adenosine triphosphate is the chief source of chemical energy for the exercising muscle. Mechanical energy is produced by the process of excitation-contraction coupling, driven by the breakdown of adenosine triphosphate and the release of inorganic phosphates and adenosine nucleotides. The stores of adenosine triphosphate and phosphocreatine in the myocytes are sufficient only for 10 to 15 seconds of activity, and so must continuously be replenished. As can be seen in Figure 20-2, adenosine triphosphate is produced in small amounts in the cytosol by anaerobic metabolism. Much larger amounts are produced aerobically in the mitochondria.^{3,5}

Anaerobic and aerobic metabolic activities use glucose, which is metabolised to pyruvate. Pyruvate then has two possible fates. It may be converted into lactic acid, and excreted into the bloodstream, where it is buffered by sodium bicarbonate converting it to lactate. This reaction results in the production of carbon dioxide and water, along with small amounts of adenosine triphosphate, and the former are excreted in the lungs. The lactate molecule is taken up by the liver for resynthesis to glucose and glycogen, which can then be utilised again for energy production.

The other fate of pyruvate is aerobic metabolism. Pyruvate is converted into acetyl-coenzyme A and transported into the mitochondria where it enters the Krebs cycle, again producing carbon dioxide and water. Adenosine triphosphate is produced in large quantities via the

Figure 20-1 An illustration of the functional interdependence of the multiple systems of organs during exercise. The meshing gears represent the musculoskeletal and the cardiopulmonary systems, which interact to assure adequate delivery of oxygen to, and removal of byproducts from, the exercising muscles. The smooth continuous interactions of these multiple physiological systems are essential for proper function of the muscles during exercise. See the text for detailed discussion. Philadelphia: Lea & Febiger 1994, pp 1-8.)

electron transport chain, with oxygen functioning as the terminal electron acceptor. Unlike anaerobic metabolism, fats as well as carbohydrates and proteins can undergo aerobic metabolism. Fats enter aerobic metabolism at the level of the Krebs cycle, and do not undergo anaerobic metabolism.^{4,5}

During any activity, the availability and use of substrates, primarily fats or carbohydrates, will vary depending upon the type, intensity, and duration of activity. Fats are more reduced than carbohydrates, requiring more oxygen for complete oxidation compared to carbohydrates on a mole for mole basis.⁴ The ratio of production of carbon dioxide to consumption of oxygen, abbreviated to $\dot{V}_{CO_2}/\dot{V}_{O_2}$, is called the ratio of respiratory exchange, or if in a steady state, the respiratory quotient. In a state of high use of fat, the ratio is approximately 0.7. Conversely, during pure carbohydrate metabolism, the ratio is 1.0, reflecting the lower amount of oxygen needed to oxidise carbohydrates. The stores of glycogen in the adult body are seldom more than approximately 1500 Kcal. Some use of fat, therefore, is almost always required. As a result, the resting ratio of respiratory exchange, even in the well-fed state, will usually range from 0.8 to 0.9.

During a typical graded maximal exercise test, the work rate is gradually increased over the course of 10 to 15 minutes, as explained in our subsequent sections concerning exercise protocols. Production of adenosine triphosphate will need to increase as mechanical work increases, and at low levels of work this increase is met predominately by increased aerobic metabolism. Slow twitch muscle fibers, so-called Type 1, with high oxidative metabolism, are primarily recruited for this activity. As work rate increases, consumption of oxygen increases in a linear fashion (Fig. 20-3). Near peak work rates, consumption will tend to plateau, as maximal consumption is achieved. This phenomenon is often absent in children.^{4,6,7}

As consumption of oxygen increases in response to increased work rate, there is a gradual rise in the ratio of respiratory exchange. The reason for this rise is twofold. First, there is a gradual shift in use of fats compared to carbohydrates. This shift allows for more efficient use of

oxygen, as the yield of adenosine triphosphate per mole of oxygen is greater with carbohydrates. Secondly, the rise in the ratio occurs as a result of increased levels of lactate in the blood. At approximately 50% to 60% of the maximal consumption of oxygen, levels of lactate begin to rise in the serum. The point where clearance can no longer keep up with production is known as the lactate threshold. The onset of anaerobic metabolism by the exercising muscles is responsible for this production of lactate. Above the threshold, levels of lactate rise exponentially as work rate increases, necessitating increased buffering by sodium bicarbonate in order to maintain blood pH homeostasis. The byproduct of the buffering process, carbon dioxide, must be removed in order to maintain levels within the normal range. This causes a significant rise in production of carbon dioxide out of proportion to the rise in consumption of oxygen, resulting in the respiratory exchange ratio increasing to greater than 1.0. The ratio in adults at peak exercise may be as high as 1.2 to 1.4, but is usually somewhat lower in children.⁶⁻¹¹

The increase in production of carbon dioxide associated with the buffering of lactate allows for measurement of a non-invasive surrogate of the lactate threshold. This surrogate, known as the ventilatory anaerobic threshold, is defined as the point where production of carbon dioxide, and minute ventilation, begin to rise out of proportion to the consumption of oxygen. Like the lactate threshold, the ventilatory anaerobic threshold occurs at approximately 50% to 60% of the maximal consumption of oxygen. It may be significantly lower or higher in de-conditioned or highly trained athletes, respectively. Like maximal consumption of oxygen, the ventilatory anaerobic threshold is a physiological limit, and has been used as a marker of aerobic fitness. Unlike maximal consumption of oxygen, the ventilatory anaerobic threshold has the virtue of being effort independent, is a level of exercise that can be sustained over a prolonged period of time, and is easily affected by training or sedentary behavior. Unfortunately, the ventilatory anaerobic threshold can be difficult to measure accurately in smaller children who tend to have erratic patterns of breathing.⁶⁻¹¹

Figure 20-2 An illustration of cellular respiration, which results in the release of the energy of the terminal phosphate bond of adenosine triphosphate to fuel the contractile and related demands of the working skeletal muscle. (Reprinted with permission from Astrand P, Rodahl K: The Muscle and Its Contraction. Textbook of Work Physiology, Physiological Bases of Exercise, Third Edition. McGraw-Hill, Inc. 2:12-53, 1986).

Figure 20-3 The relationship between consumption of oxygen V_{O_2} and rate of work during progressive exercise in a healthy and well-conditioned adolescent. Note that, with the onset of exercise, there is an essentially linear relationship between these two features. Close to the peak of exercise, the consumption of oxygen levels off, despite the continued rise in rate of work (see text for detailed discussion).

THE HEART AND LUNG AS SERVICE ORGANS

As previously mentioned, consumption of oxygen rises in near linear response to increasing work rate. The consumption can be derived from the Fick equation as follows:

$$V_{O_2} = Q \times (a - v O_2 \text{ diff.})$$

where V_{O_2} is consumption, Q is cardiac output, and $a - v O_2$ diff. is the difference in content of oxygen is arterial and mixed venous blood. Q is defined as:

$$Q = SV \times HR$$

where SV is stroke volume and HR is heart rate. Rearranging the equations, we see that V_{O_2} is:

$$V_{O_2} = SV \times HR \times (a - v O_2 \text{ diff.})$$

The rise in consumption of oxygen during exercise, therefore, is dependent on the increases in stroke volume and heart rate, and widening of the difference in the content of

Figure 20-4 The relationship of heart rate and stroke volume to increasing consumption of oxygen during cycle ergometry in 23 male and female subjects. Note that stroke volume reaches its maximal value at approximately 30% to 40% of the maximal uptake of oxygen. Heart rate continues to rise in a linear fashion throughout exercise. (Reprinted with permission from Astrand P, Rodahl K: *The Muscle and Its Contraction*. Textbook of Work Physiology, Physiological Bases of Exercise, 3rd ed, Vol. 2. New York, McGraw-Hill, Inc., 1986, pp 12–53.)

oxygen in arterial and mixed venous blood. During strenuous exercise, cardiac output may rise as much as fivefold over resting levels.^{5,12–15} Both stroke volume and heart rate contribute to this increase, but the relative contributions of each are different.⁵ At rest, stroke volume is approximately 60% of its maximal value. At the onset of exercise, a combination of increased venous return and sympathetic tone causes stroke volume to increase. This occurs as consequence of two mechanisms. First, increased preload stretches the myocyte and increases tension, resulting in changes in the Frank–Starling forces. Second, the increase in sympathetic tone results in an increase in the inotropic state of the myocardium. This increase in inotropy improves the active tension developed for any given preload, thus further augmenting stroke volume. Most of the increase in stroke volume takes place below 30% to 40% of the maximal consumption of oxygen (Fig. 20-4). At higher heart rates diastolic filling time is decreased, which limits any further augmentation in stroke volume irrespective of any increase in the inotropic state. Therefore, at higher heart rates, and naturally at higher work loads, the relative contribution of stroke volume to the overall increase in cardiac output is small.

An increase in heart rate is the primary mechanism for the increased cardiac output at higher work rates. This is reflected in the essentially linear relationship between heart rate and consumption of oxygen as work rates increase (see Fig. 20-4). The ability to increase heart rate in a normal manner during exercise, therefore, is essential to achieving a normal aerobic workload. The difference in content of oxygen between the arterial and mixed venous blood gradually widens with increasing work rate and consumption

of oxygen, as a result of increased extraction of oxygen by the exercising muscles. The byproducts of myocytic metabolism, including hydrogen, carbon dioxide, and lactate, all lower the pH, thereby shifting the oxygen-haemoglobin dissociation curve rightward, favouring increased unloading of oxygen at the level of the exercising muscle. Such unloading is more pronounced at higher intensities of exercise, when the concentration of metabolic byproducts is greater. This will be discussed in more detail below in the relationship between consumption of oxygen and cardiac output.

DISTRIBUTION OF BLOOD FLOW

For consumption of oxygen to increase during exercise, it is essential that cardiac output not only increase, but that blood flow is preferentially shunted to the exercising muscles (Fig. 20-5). At peak exercise, blood flow to exercising muscle may be 80% or more of the total cardiac output. The redistribution of blood flow is achieved by a combination of autonomic and metabolic vasoregulatory mechanisms.¹⁶ Exercise is essentially a state of increased sympathetic nervous system tone, which is regionally overridden by metabolic vasodilation. The increase in sympathetic tone associated with exercise results in a generalised constriction of the precapillary resistance arterioles. Simultaneously, the sympathetic tone increases heart rate and cardiac contractility, resulting in increased cardiac output.^{16–18} Vasodilation occurs at the level of the exercising muscle as a result of local metabolic changes. Aerobic and anaerobic metabolism, excitation-contraction coupling, and breakdown of adenosine triphosphate all result in the release of potent vasodilators into the interstitial spaces. These vasodilators include free potassium and hydrogen ions, carbon dioxide, lactate, adenosine diphosphate, and inorganic phosphate. The result is a profound vasodilation of the vascular bed in the exercising muscles.

Vasoconstriction of the splanchnic vascular bed results in either no change, or a decrease, in flow of blood to the gut and kidneys. The effect on the overall peripheral vascular resistance depends on the size of the exercising muscle groups. During dynamic exercise, which utilises large muscle groups, such as running, the net result is a significant drop in systemic vascular resistance, despite an overall increase in sympathetic tone.

SURROGATES OF CARDIAC OUTPUT

Exercise testing is frequently performed in order to assess the ability of the cardiovascular system to increase cardiac output in response to an increased workload. Measurement of cardiac output during exercise, however, is often not practical. Direct measurements are too invasive to allow adequate levels of exertion. Non-invasive methods are often technically difficult, and may be inaccurate in the pathophysiological states that are encountered in many types of congenitally malformed hearts. The obstacles accurately and reliably to measure cardiac output has led to the use of consumption of oxygen as a surrogate of cardiac output in many clinical and research settings.^{4,16,19} Over a broad range of consumption of oxygen there is a nearly linear relationship between consumption of oxygen and cardiac output (Fig. 20-6).

Figure 20-5 The parallel circuits of flow through the various systems of organs, both at rest and during peak exercise. Note that the cardiac output increases by approximately fivefold from rest to strenuous exercise. The relative distribution of flow to the various systems, in contrast, is significantly different from rest to peak exercise. In both states, the red squares are proportional to the percentage of cardiac output received by the particular system. Note that the flow of blood to the muscle increases from between approximately 15% to 20% of cardiac output at rest to 80% to 85% of the cardiac output at peak exercise. (Reprinted with permission from Astrand P, Rodahl K: *The Muscle and Its Contraction*. Textbook of Work Physiology, Physiological Bases of Exercise, 3rd ed., Vol. 2. New York: McGraw-Hill, Inc., 1986, pp 12–53.)

Figure 20-6 The relationship of cardiac output to consumption of oxygen measured in 23 subjects during sitting cycle ergometry. These data are from the same subjects shown in Figure 20-4. See text for discussion. (Reprinted with permission from Astrand P, Rodahl K: *The Muscle and Its Contraction*. Textbook of Work Physiology, Physiological Bases of Exercise, 3rd ed., Vol. 2. New York: McGraw-Hill, Inc., 1986, pp 12–53.)

Despite a plateau in cardiac output at very high work loads, consumption of oxygen continues to increase as a result of increased oxygen extraction, thereby increasing the arterial-mixed venous content of oxygen difference. Consumption of oxygen is determined by the amount of oxygen delivered in the blood that is extracted by the metabolically active tissues. During exercise, this extraction is determined by the myoglobin content of the exercising muscle, the isoenzyme characteristics of the muscle, as well as the physiological milieu in which the muscle is working.^{4,16} The physiological state will have a great impact on the oxygen-haemoglobin dissociation curve. As previously stated, there are multiple byproducts of muscle metabolism which are released into the intercellular space during exercise, shifting the oxygen-haemoglobin dissociation curve to the right.⁴ The local increase in muscle temperature during exercise also has the same effect. The net result is an increase in oxygen unloading to the exercising muscle particularly at high workloads. There is therefore an increase in the arterial-mixed venous content of oxygen difference, and a continued rise in consumption of oxygen, even in the presence of a flattening or plateauing of the rise in cardiac output near peak exercise.^{4,16,17}

Gender differences are present in the relationship between cardiac output and consumption of oxygen (see Fig. 20-6). Females tend to have a somewhat higher cardiac output for any given consumption, as well as a lower maximal consumption.¹⁷ These differences are likely due to the difference in content of haemoglobin between males

and females. Females have lower levels of haemoglobin in the serum compared to males, and therefore have lower contents of oxygen, necessitating a higher cardiac output to deliver an equivalent consumption of oxygen. Lower values in adolescent and adult females manifest clinically in slightly higher cardiac outputs, and lower consumption of oxygen at peak exercise. It is easy to comprehend how anaemia will result in reduced consumption of oxygen and a higher ratio of cardiac output to consumption of oxygen compared to non-anaemic states. The use of consumption of oxygen as a surrogate for cardiac output, therefore, is problematic in the presence of anaemia.

OXYGEN PULSE

In a clinical setting, the practitioner is frequently interested in assessing the intrinsic inotropic state of the myocardium during exercise. As was stated earlier, this state is primarily reflected by the stroke volume of the heart. A non-invasive measurement of stroke volume is a useful tool to assess myocardial function. This has given rise to the use of oxygen pulse during exercise testing.²⁰

The oxygen pulse is defined as:

$$\text{Oxygen pulse} = \dot{V}O_2 \text{ in mL/min/HR}$$

Since $\dot{V}O_2 = (SV \times HR) \times (a - v O_2 \text{ diff})$, the pulse also equals:

$$SV \times (a - v O_2 \text{ diff})$$

The oxygen pulse, therefore, is a value that can be measured at any given work rate or consumption of oxygen during exercise testing. A rise or fall in stroke volume will correlate with a rise or fall in the oxygen pulse. These changes can be blunted somewhat by an increase or decrease in the difference in content of oxygen between arterial and mixed venous blood, but the ability of muscles to extract oxygen usually does not significantly change except in response to prolonged training. This is particularly true at maximal exercise. The oxygen pulse is perhaps most useful in assessing changes in myocardial performance over time, or following therapeutic interventions in an individual patient. Assuming no change in the haemoglobin content, the content of oxygen of the arterial blood should be unchanged. Absent large weight changes, the consumption of oxygen required to perform a given amount of work on an ergometer for an individual patient is constant. Any increase in the oxygen pulse measured at a given work rate, therefore, would reflect a lower heart rate needed to achieve the same consumption of oxygen, and be indicative of a higher stroke volume. The converse would be true for a falling oxygen pulse. This does presume the haemoglobin content of the blood has not changed, and that the chronotropic state of the heart is also unchanged. A significant change in either of these limits the usefulness of the oxygen pulse to act as a marker of stroke volume during exercise.

PULMONARY RESPONSE TO EXERCISE

Consumption of oxygen, and removal of carbon dioxide, require that the cardiovascular and pulmonary systems work together as a single integrated unit. The ultimate

goal is that for a given consumption of oxygen, minute carbon dioxide is eliminated while maintaining P_{aCO_2} and pH within a narrow physiological range. For this reason, it is not surprising that there is a very tight relationship between minute ventilation, consumption of oxygen, and production of carbon dioxide. Such a relationship is demonstrated in ventilatory equivalents for carbon dioxide and oxygen, namely $\dot{V}E/\dot{V}CO_2$, and $\dot{V}E/\dot{V}O_2$. The typical relationship of minute ventilation to increasing work rate, and the relationship of the ventilatory equivalents for carbon dioxide and oxygen to work rate, are depicted in Figure 20-7. Note that there is a steady rise in minute ventilation with increasing work rate. Both ventilatory equivalents initially fall at the onset of exercise and then plateau. During the plateau phase, minute ventilation is increasing in proportion to both the increases in the ventilatory equivalents for carbon dioxide and oxygen. At the onset of the ventilatory anaerobic threshold, minute ventilation begins to increase out of proportion to consumption of oxygen as the respiratory drive is stimulated by increased production of carbon dioxide occurring as a consequence of the buffering of lactic acid. Note in Figure 20-7B that, at this point, the ventilatory equivalent for oxygen begins to rise while the ventilatory equivalent for carbon dioxide remains stable. At maximal exercise, production of lactic acid may rise

Figure 20-7 A, The relationship of minute ventilation ($\dot{V}E$) to rate of work in the same subject as Figure 20-3. Note there is a steady rise in minute ventilation as rate of work increases. B, The ventilatory equivalents of oxygen ($\dot{V}E/\dot{V}O_2$) and carbon dioxide ($\dot{V}E/\dot{V}CO_2$) for the same subject. The onset of the ventilatory anaerobic threshold (VAT) and terminal hyperventilation (TV) are marked (see text for discussion).

to a level that can no longer be adequately buffered by sodium bicarbonate and frank metabolic acidosis ensues. The normal physiological response to acidosis is a marked hyperventilatory response referred to as terminal hyperventilation. At terminal hyperventilation, both the ventilatory equivalents for oxygen and carbon dioxide rise, resulting in a significant fall in PaCO_2 .^{4,8-10}

Minute ventilation is defined as:

$$\text{VE} = \text{V}_T \times \text{F}$$

where V_T is tidal volume and F is respiratory rate.

At the onset of exercise, minute ventilation initially increases primarily by an increase in tidal volume rather than respiratory rate. Tidal volume includes both alveolar ventilation as well as the physiological dead space. Physiological dead space is made up of both anatomic components, the trachea and bronchi, as well as the functional dead space, namely the ventilation of hypoperfused or non-perfused pulmonary components. At rest the ratio of dead space to tidal volume is approximately 30% to 35% in adults and adolescents. With the increase in tidal volume at the onset of exercise, the ratio falls. This is due to a larger tidal volume relative to the fixed anatomic dead space. Additionally, there is an improvement in ventilation-to-perfusion matching as the increased negative thoracic pressure causes recruitment of additional capillary beds, resulting in a fall in the physiological dead space. At peak exercise, the ratio of dead space to tidal volume may fall to approximately 5% to 15%. Children typically have less efficient ventilation than either adolescents or adults, and tend to have a higher respiratory rate for any given minute ventilation, resulting in a higher ratio at any level of exercise.²¹⁻²⁵

At higher levels of exercise, minute ventilation increases in terms of both tidal volume and respiratory rate. Much of the improvement in the ratio occurs at lower to moderate levels of work. The rapid fall in the ratio is responsible for the initial steep fall in the ventilatory equivalents for oxygen and carbon dioxide that occurs at the onset of exercise (see Fig. 20-7B). Although both consumption of oxygen and production of carbon dioxide are increasing in early exercise, this is more than compensated for by the improved efficiency of the lungs, resulting in a less than proportional rise in minute ventilation.

In healthy children and adults, ventilation is not the rate-limiting step in exercise performance.^{4,20} This is because the cardiovascular system usually reaches its limit of delivery of oxygen before the pulmonary system is exhausted. At the maximal level of exercise, most subjects have not maximally stressed their pulmonary system, and there is pulmonary reserve, which is described by exercise physiologists as the breathing reserve. This is the theoretical ability to increase minute ventilation that remains untapped at maximal minute consumption of oxygen. This value is in the range of 20% to 50% in healthy children and adults.²⁰

The breathing reserve is defined as:

$$(1 - \max \text{VE}/\text{MVV}) \times 100$$

and is expressed as a percentage, where VE is the maximally achieved VE at peak exercise and MVV is maximal voluntary ventilation.

Maximal voluntary ventilation is obtained by having the subject hyperventilate for 10 seconds as vigorously as possible prior to exercise testing. Much longer periods of rapid and deep breathing may result in fainting, and should be avoided. The volume achieved is then multiplied by six, theoretically to give a maximally achievable minute ventilation. A low breathing reserve, of less than 20%, may indicate that primary pulmonary abnormality is limiting exercise performance. As maximal voluntary ventilation is a highly effort dependent measurement, care must be taken when interpreting breathing reserve. Other confirmatory data, such as an abnormal response of the ventilatory equivalents, or abnormal resting spirometry, should be sought to confirm pulmonary abnormalities.

LABORATORY REQUIREMENTS

Environment

Adequate space and environmental controls are important in order to assure a successful exercise test. The child should be made to feel comfortable and relaxed, which will improve exercise performance. Sufficient space is needed to accommodate the various ergometers and monitoring equipment, including emergency resuscitation equipment, while maintaining adequate space to access the patient in emergency situations. A minimum of 250 square feet of space is required, with 500 square feet or more when multiple work stations are employed.²⁶

The climate of the laboratory must be well controlled to allow proper thermoregulation during the exercise test. The room should be well ventilated and temperatures should be regulated between 20° C and 23° C,^{26,27} a temperature range which permits the child to be comfortable at rest but still allows for adequate dissipation of heat during exercise. Humidity should be approximately 50% to ensure free perspiration during exercise.²⁷

The laboratory should be child-friendly. Television monitors with appropriate programming, and wall posters, have proven useful in minimising anxiety and/or boredom of the patients.

Safety Precautions

Exercise testing has been performed in children with very low risk, even in those who have complex cardiovascular disease.^{28,29} Although significant complications of exercise testing are rare, proper safety precautions are essential. Key staff usually include at least one physician who is well trained in paediatric exercise testing. A physician does not need to be present for testing patients deemed to be at low risk or healthy,^{27,30} but should be present at the testing of any child deemed to be at increased risk of a complication, such as a child with a life-threatening arrhythmia or syncope. The American Heart Association published guidelines for patients who are at low risk for exercise complications, and require a physician available, but not physically present (Table 20-1).³⁰ The risk for each patient must be individually assessed. Ideally, two staff members trained in exercise testing should be present for all tests. All exercise physiologists or exercise technicians should be familiar with paediatric exercise testing, and at least one of these personnel should be trained in paediatric advanced life support. A well-stocked emergency resuscitation cart,

TABLE 20-1**INDICATIONS FOR EXERCISE TESTING THAT MAY NOT REQUIRE A PHYSICIAN'S PRESENCE**

1. Assessment of working capacity in healthy children for research.
2. Evaluations of chest pain of non-cardiac origin.
3. Post-operative follow-up of patients with good haemodynamics to assess working capacity or rehabilitation screen.
4. Evaluation of isolated PACs or PVCs in a healthy child with a normal QTc.
5. Routine follow-up of known arrhythmias or pacemakers.
6. Kawasaki disease or other coronary abnormalities without a known history of ischemia.
7. Asymptomatic mild aortic stenosis.
8. Evaluation of asymptomatic mild congenital or acquired cardiac malformations.

From the Committee on Atherosclerosis and Hypertension in Children, Council on Cardiovascular Disease in the Young, the American Heart Association. *Circulation* 1994; 90:2166–2179.

defibrillator, system for delivery of oxygen, and suction apparatus are also essential.³⁰

Preparation of Patients

Education and preparation of the children before and during their test are probably the most important factors in successful testing. A thorough explanation of the testing procedure results in better compliance and effort, especially in younger children. Children should avoid heavy meals for approximately 2 hours prior to the test, and wear appropriate clothing, such as shorts, T-shirts, and athletic shoes. Proper preparation of the skin helps to ensure an adequate electrocardiographic signal.³¹ Superficial abrasions should be performed to remove the top layer of epidermis and enhance the electrical signal. Electrodes should be large enough to provide a good contact with the skin.

The patient should be instructed in the procedures to be used during the exercise test. These include proper use of the treadmill or cycle ergometer, and the use of hand signals to convey the level of fatigue, distress, or symptoms. Scales of perceived exertion, such as the Borg scale,

can be useful in communicating with the child during the study. Such scales allow those conducting the testing to estimate when the child is likely to reach maximal effort (Fig. 20-8).³² Special attention should be given to maneuvers, such as spirometry or inert gas rebreathing, that require proper technique and cooperation from the patient.

EQUIPMENT**Ergometers**

In most paediatric exercise laboratories, testing is primarily directed toward measuring aerobic capacity. Therefore, ergometers should generate work in the large muscle groups. The two types of ergometers most commonly used are the motorised treadmill and the upright cycle ergometer. The choice of ergometer depends on the type of information desired, but there are both advantages and disadvantages to each modality (Tables 20-2 and 20-3).^{33–35} It is therefore best that a laboratory be equipped to perform testing using either type of ergometer.

Treadmill

The treadmill is the most common ergometer in the paediatric exercise laboratory.

TABLE 20-2**MATCHING THE PROTOCOL WITH THE DESIRED INFORMATION**

Condition or Question	Cycle Ergometry	Treadmill	Rationale
Aortic stenosis/insufficiency	Preferred		Electrocardiographic assessment for ischemia easier due to less motion artifact
Repaired transposition of great arteries	Preferred		Electrocardiographic assessment for ischemia or arrhythmia easier
Repaired tetralogy of Fallot	Preferred		Arrhythmia assessment during exercise essential
Coronary arterial anomaly (pre or post repair)	Preferred		Electrocardiographic assessment for ischemia
Single ventricle/Fontan	Either	Either	Dependent upon query
Coarctation of the aorta	Preferred		Blood pressure assessment more accurate
Exercise-induced asthma/bronchospasm/chest pain		Preferred	Running more likely than cycling to induce symptoms
Aerobic fitness		Preferred	Higher Vo_2 with treadmill compared to cycle
Arrhythmia Assessment/long QT	Preferred		Less motion artifact on ECG

TABLE 20-3

TREADMILL VERSUS CYCLE ERGOMETER

Features	Treadmill	Cycle
Patient familiarity	+	
Higher work rates and oxygen consumption	+	
Greater paediatric experience		+
Quantification of work performed		+
ECG and blood pressure artifact		+
Safety		+
Expense		+
Noise		+

The biggest advantage of the treadmill compared to the cycle ergometer is the familiarity that children have with walking or running.³⁵ Furthermore, more muscle groups are utilised with treadmill testing, resulting in a greater stress on the cardiovascular system and higher consumption of oxygen. Consumption of oxygen, and the oxygen pulse, are on average higher by one-tenth with treadmill testing compared to the cycle.³⁴

The treadmill also has several distinct disadvantages. It is noisy, and may frighten small children. The increased movement from vigorous running results in much greater distortion of electrocardiographic and blood pressure signals compared to the cycle. The treadmill also requires more space, is not portable, and there is a danger of falling off of the moving platform. Care must be taken to ensure that the patient is closely monitored, and does not attempt to get off of the treadmill abruptly. Another disadvantage of the treadmill is the inability accurately to determine rate of work. The latter disadvantage is less of a clinical than a research concern, where an accurate measurement of rate of work is desirable (see Table 20-2).

Treadmill Protocols

The Bruce protocol and its modifications are the most commonly used protocols in the paediatric exercise laboratory.³⁵ This protocol consists of 3-minute stages, with an increase in both speed and grade of the treadmill at each stage. Despite its popularity, the incremental increases in work load for the Bruce protocol are large even when modified for children. This frequently makes the shift in rate of work between stages difficult for younger children. The relatively long stages also make more difficult interpretation of metabolic data from analysis of expired gases. The graphic displays of various metabolic measurements, such as consumption of oxygen versus time, are not linear but rather appear as a series of slopes followed by partial plateaus. Such non-linear graphic displays makes determination of key parameters of exercise performance, such as the onset of ventilatory anaerobic threshold, more difficult than in protocols with a continuous increase in work load.

In the last decade, the protocols with shorter stages, usually of 1 or 2 minutes, and smaller incremental increases in rates of work, have gained popularity. These protocols, such as the Balke treadmill protocol, may use a fixed speed, with increases only in grade, or may increase both speed and grade. These protocols can also be modified according to the age, size, and physical conditioning level of the child being tested, thereby

Figure 20-9 The panels show the protocols for testing using a treadmill. A, The Bruce protocol, which consists of 3-minute stages with an increase in both speed and grade. The first two stages are often omitted in healthy adult testing. B, The Balke protocol: The grade is increased from 0 to 2% after the first minute, and increased 1% in each subsequent minute. The speed of the treadmill is held constant at 3.5 mph.

allowing the total exercise time to be relatively constant for all subjects. Such a relatively constant duration of exercise is important because previous studies have demonstrated that total testing for more than approximately 12 to 15 minutes is associated with decreased aerobic performance, due to both shunting of blood to the skin for thermoregulation, and poor motivation caused by boredom. A total time of less than 10 minutes may result in poor aerobic performance, because the patient ceases exercising due to excessive muscle fatigue caused by the higher rates of work.³⁴ The Bruce and Balke protocols are summarised in Figure 20-9.

Cycle Ergometers

These machines have several significant advantages compared with treadmills. A distinct advantage is decreased distortion of electrocardiographic and blood pressure recordings, particularly crucial when there are concerns about arrhythmias, ischaemia, or changes in morphology of the QRS complexes. The cycle also accurately measures external work performed during the test. This requires that the rate of work be relatively independent of speed of pedalling. The ergometer should be regularly calibrated, and carefully assessed before its use, in light of signal-to-noise ratio on some cycles, which may be excessive at the low initial rates of work used in paediatric protocols. Low signal-to-noise ratios are not common problems in the newer generation of cycles, that use digital rather than analogue controllers of the rate of work. Other advantages of cycle ergometers include lower cost, portability, and

increased safety. Musculoskeletal injuries are also less likely with a cycle.³⁴

Disadvantages, as stated previously, include a generally lower achieved level of exertion and maximal consumption of oxygen. In addition, the current generations of cycles are frequently unable to accommodate younger children who are less than 130 cm in height. The crank arm is frequently too large for these small children. Ergometers used for testing children, therefore, should have an adjustable crank arm. Several cycle ergometers are commercially available with paediatric modifications.

Protocols

The most commonly used protocol is that devised by James, which consists of 10 stages, each lasting 3 minutes.³⁶ The incremental increases for each stage vary depending upon body surface area. The James protocol has been extensively validated for use in children over the last two decades,^{35–37} and hence has well established normative data. Its major disadvantage is the difficulty of analysing metabolic data with its long 3-minute stages, similar to those encountered with the Bruce protocol.

Collection of expired gas is such a common occurrence that many laboratories are now using ramp cycle protocols. In this protocol, the rate of work is increased in small, frequently single-watt, increments, thus producing a smooth continuous rise throughout the test.^{26,34,35} These protocols have several advantages. First, the gradual rise in rate of work avoids problems encountered with the large sudden jumps seen when using 3-minute increments. Second, the slopes of the ramps are seamlessly adjusted to accommodate a wide range of sizes, ages, and levels of physical conditioning. Third, relationships between metabolic data and rate of work are easier to appreciate with this type of protocol. The two protocols are shown in Figure 20-10.

Electrocardiographic Recorders

Many high-quality commercial electrocardiographic recording systems are currently available. No system currently available is designed specifically for paediatric use, but all are generally acceptable without modification. Minimisation of distortion of signals is accomplished with computer digitisation of the analogue electrical signal. The printer should use a direct writer mechanism.³¹

A liquid crystal or cathode ray tube display is essential so that the rhythm, and morphology of the QRS complexes, can be monitored continuously. The display should show at least one, and ideally multiple, leads continuously. The technician obtains a complete 12-lead recording at set time intervals, usually of 1 minute, and when needed during the course of an exercise test. Ideally, all QRS complexes should be stored, either as a hard copy or digitally.²⁶ Automated devices are available on many recorders to detect arrhythmias, and are useful, except when there are abnormal QRS complexes, pacemaker generated complexes, or if significant motion artifact is present.

Most computerised recorders have algorithms that will average the recorded signals, thus eliminating baseline drift and background artifact, permitting easy interpretation of changes in the QRS and ST segments. It is possible that data may be lost with certain algorithms at very high heart rates, so it is important to compare the averaged to the raw data when interpreting the test.

Figure 20-10 Protocols for use with an upright cycle ergometer. A, The James protocol. The initial rate of work is 200 kpm/min. The rate is increased every 3 minutes by different amounts, depending on the body surface area of the patient (BSA). B, The Ramp protocol. The patient initially pedals for 3 minutes with unloaded cycling to establish a baseline metabolic state. The rate of work is then increased continuously at a chosen level based on the physical condition, age, and size of the patient.

Analysers of Exchange of Respiratory Gases

The use of these analysers has become routine in laboratories studying paediatric exercise physiology. Measurements of consumption of oxygen, production of carbon dioxide, as well as pulmonary functions such as minute ventilation, tidal volume, and respiratory rate, are easily obtainable. Several systems at reasonable prices are commercially available. In addition to measuring expired gases, these systems are frequently equipped to perform resting spirometry, and to receive input from other sources, such as an electrocardiographic recorder. This allows a single system to generate complete and final reports.

Analysers using inert gases can be used to estimate cardiac output.³⁸ The patient breathes room air during most of the test. During the measurements of cardiac output, ventilation is diverted via a valve into a closed system, usually through a 3-liter rebreathing bag, containing a mixture of oxygen, an inert diffusible gas, and an inert non-diffusible gas. After one to two breaths, the non-diffusible gas equilibrates between the lungs and the bag, and the final concentration of this gas can be used to calculate the volume of the lungs. The diffusible gas is removed from the system in proportion to the flow of blood to the lungs. The assumption when assessing cardiac output is that flows are equal in the pulmonary and systemic circulations,

with a bag volume of 1900 mL.←, →, +, - - Move Cursor, SPACE BAR - Select Point. <, > - move start
(.) - move end. ENTER - Calculate Q. ↑↓ - Axis Scale. ESC - Exit

Figure 20-11 This figure displays a noninvasive measurement of cardiac output using the diffusible gas technique. Time is on the x-axis, and the natural log of the concentration of the diffusible gas, in this case acetylene, is on the y-axis. The lower curve shows the concentration of helium that equilibrates between the lungs and the rebreathing bag after several breaths. This allows calculation of the lung volume. The slope of the decay of the acetylene is calculated from the top curve, and is used to measure the flow of blood to the lungs that should equal systemic cardiac output, in this case 11.26 L/min, in the absence of pulmonary disease or intracardiac shunting.

and there is no significant intrapulmonary or intracardiac shunting. The calculated flow of blood to the lungs then reliably estimates systemic cardiac output. Unfortunately, residual pulmonary and/or intracardiac shunts frequently limit the usefulness of this measurement. Such assessment also requires cooperation from the patient, and expertise of tester in performing the rebreathing maneuvers correctly.

Acetylene and helium are commonly used inert soluble and insoluble gases, respectively. A mass spectrometer is usually required (Fig. 20-11). These systems are considerably more expensive than most commercially available metabolic carts, and are typically designed by the individual laboratories using them. Compact, commercially available, systems have come on the market in the last decade. They are less costly, and more user-friendly, than individually designed systems. Alternatively, rebreathing of carbon dioxide is commonly employed in commercially available systems. The latter system uses the indirect Fick method to estimate cardiac output. A number of assumptions are necessary in order to estimate arterial partial pressures of carbon dioxide,^{38,39} which may result in significant inaccuracies in children with congenital cardiac disease. The rebreathing method also has the disadvantage of requiring steady state minute ventilation, and therefore is not suitable for protocols with frequently changing rates of work.

Methods for noninvasive measurement used less frequently with exercise testing include electrical bioimpedance and Doppler measurement of aortic blood flow.^{38,39} Bioimpedance has the advantage of requiring very little cooperation from the patient, albeit that studies comparing this method with diffusible gas methods have shown poor correlation.³⁹ Correlations of Doppler with diffusible gas methods are superior to bioimpedance, but obtaining

an adequate Doppler signal with exercise remains a cumbersome undertaking.

Spirometry

Essential measurements include basic inspiratory and expiratory flow volume loops, and assessment of maximal voluntary ventilation. Maximal voluntary ventilation is measured by the sprint method as outlined by the American Thoracic Society, wherein maximal ventilation is measured for an interval of 10 to 15 seconds, and extrapolated to 1 minute.⁴⁰ Spirometry is used to identify patterns of obstructive or restrictive pulmonary disease that could impair exercise performance. Post-exercise spirometry is useful for identifying patients with exercise-induced bronchospasm. Maximal voluntary ventilation is used in the assessment of the remaining pulmonary capacity at the end of exercise, the breathing reserve. As already discussed, this is the fraction of the capacity of the pulmonary system to increase minute ventilation at maximal exercise, with normal values ranging from 20% to 50%. In situations of testing where the maximal voluntary ventilation sprint method is not feasible, it may be estimated using any one of the following equations:

$$MVV = FEV_1 \times 35^{41}$$

$$MVV = FEV_1 \times 40^{42}$$

$$MVV = 27.7(FEV_1) + 8.8(\text{Pred } FEV_1)^{43}$$

where MVV is maximal voluntary ventilation, and FEV_1 is forced expiratory volume in 1 second.

Although widely accepted as accurate in healthy adults, not all of the above equations have been validated in healthy

children, albeit that the first equation has been validated in healthy African-American adolescent girls. Whenever possible, therefore, maximal voluntary ventilation should be determined using the sprint method as recommended by the American Thoracic Society.

Blood Pressure Monitors

Monitoring of blood pressure has been a significant problem during exercise testing due to artifact from motion of the arm, making accurate measurements difficult to obtain.²⁶ This is a greater problem with treadmill than with cycle ergometry. Automated systems designed for exercise testing incorporating a sensitive microphone positioned over the brachial artery are now commonly used in many laboratories. Many of these systems simultaneously receive an electrocardiographic signal, allowing precise gating to the QRS complex while filtering background noise. These systems generally measure pressure both oscillometrically and, using head phones, by direct auscultation. Direct auscultation is the preferred method, as there is a tendency to overestimate systolic and underestimate diastolic pressures with oscillometric measurements. Several sizes of blood pressure cuffs are necessary equipment.³⁰ Most automated systems also have paediatric-sized cuffs, as well as oversized cuffs for large subjects.

Oximeters

Oximeters fitted for the finger or ear are used to measure arterial saturation of oxygen. The devices are frequently inaccurate, particularly at high rates of work when children are prone to grasp the cycle handlebars too tightly.²⁶ Therefore, ear oximetry is better for laboratories using primarily cycle ergometry. All oximeters are less accurate at higher rates of work due to excessive motion.²⁶

INDICATIONS FOR EXERCISE TESTING

These depend upon symptoms, and/or the presence of cardiovascular disease. The American Heart Association issued guidelines for indications for stress testing in children (Table 20-4).³⁰ We will discuss some of the more common reasons.

Evaluation of Overall Exercise Performance in Structural Heart Disease

Evaluation of the overall performance of the cardiovascular, pulmonary, and musculoskeletal systems in children with structural heart disease may be the most common indication for testing. The goals of such evaluations primarily consist of identifying potential causes of exercise intolerance, stratification of risk for patients who have significant structural defects, and assessment of the physical capacity of postoperative patients. The data obtained may be helpful in the decision process regarding therapeutic intervention, restriction of physical activity, and programmes for rehabilitation or conditioning.

Evaluation of Rhythm

Evaluation of the heart rate response and exercise-induced arrhythmias is essential in selected patients with surgically repaired congenital defects, and in patients with known or

TABLE 20-4

INDICATIONS FOR PERFORMING AN EXERCISE TEST

1. Evaluate specific symptoms or signs induced by exercise.
2. Identify abnormal adaptive responses to exercise in cardiac or non-cardiac disorders.
3. Assess the effectiveness of medical or surgical interventions.
4. Assess functional capacity for vocational, recreational, and athletic recommendations.
5. Discover prognosis for a specific disorder.
6. Evaluate overall physical fitness levels.
7. Establish baseline data for follow-up of rehabilitation programs.

Adapted from Washington RL, Bricker JT, Alpert BS, et al: Guidelines for exercise testing in the pediatric age group. From the Committee on Atherosclerosis and Hypertension in Children, Council on Cardiovascular Disease in the Young, the American Heart Association. *Circulation* 1994; 90:2166–2179.

suspected arrhythmias. Increasingly, exercise testing is used to assess the efficacy of pacemakers, and to help modify settings in order to improve exercise performance.

Evaluation of Myocardial Ischaemia

This is a common reason for referral for exercise testing, particularly with left-sided obstructive lesions, such as aortic stenosis.³¹ In addition, a growing number of patients may be at risk for coronary arterial insufficiency after the arterial switch procedure.⁴⁴ Evidence of abnormal myocardial perfusion as a result of Kawasaki disease is also not a rare finding.⁴⁵ Less common anomalies, such as anomalous origin of the coronary arteries, and coronary arterial fistulas, place the subendocardium at risk.⁴⁶

Evaluation of Exercise-Induced Symptoms of Uncertain Etiology

One of the largest groups of patients seen in the exercise physiology laboratory is children who have various exercise-induced symptoms without a clearly identifiable source. Exercise testing may be useful in identifying potential aetiologies of symptoms. Exercise-induced dyspnoea, or new onset of exercise intolerance and fatigue, may be due to non-cardiac causes, such as pulmonary, musculoskeletal, or haematological disorders. Evaluation of exercise-induced syncope or near-syncope may result in the diagnosis of cardiac arrhythmias.

Evaluation of Exercise Capacity with Chronic Illness

The treatment of certain illnesses, such as childhood cancer, requires long and sometimes debilitating therapy. The chronic effects of therapy, at times cardiotoxic as with adriamycin, are highly variable. Evaluation of the exercise capacity in these patients is valuable in identifying cardiovascular impairment, as well as for implementing rehabilitation therapy.

DATA OBTAINED DURING EXERCISE TESTING

During each exercise test, obtaining as complete a set of data as possible is essential. Occasionally, compromises are made regarding collectable data, especially in very young

patients. Nevertheless, it should be possible to obtain the data listed below.

Rate of Work

The rate of work, or power, is measured in kiloponds for each meter per minute (kpm/min), or more commonly in watts.⁴⁷ The maximal rate can be measured directly on a cycle ergometer. The measurement must be inferred when a treadmill is used based on height and weight as well as the speed and grade of the treadmill. For this reason, when using a treadmill, it is often easier to use the exercise time for analysis rather than the rate of work, comparing the time to normal values based on age, height, and gender.

Normal values for maximal rate in healthy children are approximately 3.5 watts/kg in boys, and 3.0 watts/kg in girls.³⁵ These values appear to be relatively constant throughout the paediatric age range. In the absence of other measurements, maximal rate provides only limited information. The rate of work is reassuring if it falls within the normal range. Low values, however, do not give any information as to the cause of the limited rate. Measurements of aerobic capacity, therefore, and the ventilatory anaerobic threshold, are often more useful in the evaluation of exercise performance.

Aerobic Capacity

These values are generally presented as maximal consumption of oxygen, and the consumption of oxygen at the onset of the ventilatory anaerobic threshold. Large variations in these measures are secondary to body size. Because of this, the values are generally normalised for body weight: milliliters of oxygen consumed per minute per kilogram of body weight ($\text{mL} \cdot \text{kg} \cdot \text{min}^{-1}$).

Maximal consumption of oxygen in children varies depending on the type of protocol and ergometer used and, to a lesser extent, on the age range of the subjects.^{37,48–50} As stated previously, values obtained on a treadmill are roughly one-tenth higher than with a cycle ergometer. Normal values for children using a ramp cycle protocol are shown in Table 20-5.²⁹

In light of the broad range of maximal measurements of consumption of oxygen in children, it is difficult to

determine if an individual value for maximal consumption represents the highest achievable Vo_2 . In studies of adults, maximal consumption frequently levels off, or plateaus, at higher rates of work.⁵¹ This finding has been useful in ensuring that achieved maximal consumption truly represents the maximal aerobic capacity. This phenomenon is less likely to occur in children,⁵² hence it is necessary to use other methods to assess maximal aerobic effort. The measurement of the ratio of respiratory exchange is useful for this purpose, this ratio increasing from a normal resting value of approximately 0.8 to about 1.2 as a result of the exchange of increasing volumes of carbon dioxide. A maximal ratio of approximately 1.2 is a good indication of maximal aerobic effort.

Many children with minor structural cardiac disease, either repaired or unrepaired, will have maximal consumption of oxygen similar to that of their healthy peers.⁵³ Children with significant structural abnormalities, in contrast, even if completely repaired or palliated, seldom have normal aerobic capacity. It is nevertheless important to measure aerobic capacity in this group, as it may prove useful in the functional assessment of the surgical repair or palliation, particularly when compared to patients who have similar congenital defects. Values for aerobic capacity are available for most large groups of patients with different structural defects.^{54–61} These latter values are frequently more useful in assessing the success of a palliation in a complex defect, such as functionally univentricular physiology, than exercise data from healthy control populations. Serial comparison of aerobic capacity in an individual is also useful in assessing changes in haemodynamic state, as well as assessing the success of any therapeutic intervention.

Ventilatory anaerobic threshold is frequently expressed relative to the maximal consumption of oxygen. This value in children is in the range of 55% to 65% of the maximally achieved consumption of oxygen (see Table 20-5).⁴⁹ The ventilatory anaerobic threshold has been used less in children as a marker of aerobic fitness compared to maximal consumption of oxygen. It does have some advantages over maximal consumption of oxygen for this purpose. First, the ventilatory anaerobic threshold is a more accurately measured and repeatable measurement because it is not as effort dependent as maximal consumption of oxygen. Second, this value may have more physiological significance than maximal consumption of oxygen. The ventilatory anaerobic threshold represents, to an extent, the maximal amount of work an individual can sustain for a prolonged period of time. It is a useful guide, therefore, in assessing the ability to perform a given task. A difficulty with using this threshold to assess aerobic fitness is that it requires accurate measurement of a stable ventilatory pattern. This may be difficult to achieve, particularly in young children. The sense of dyspnoea associated with the onset of the anaerobic threshold can often result in erratic patterns of breathing in young children. As a whole, the ventilatory anaerobic threshold may not be measurable in one-fifth of children.⁶²

In studies of children with structural cardiac disease, the threshold is low when compared with healthy populations. If expressed as a percentage of the maximal consumption of oxygen, the percentage values are similar in patients with structural defects compared to the healthy population, being in the range of 55% to 65%.^{63–65} The threshold can be used by the providers of healthcare to set safe work

TABLE 20-5

NORMAL VALUES FOR AEROBIC CAPACITY IN CHILDREN AND ADOLESCENTS USING CYCLE ERGOMETRY

	BOYS		GIRLS	
	≤13 Years	>13 Years	≤11 Years	>11 Years
Maximal Vo_2 ($\text{mL} \cdot \text{kg} \cdot \text{min}^{-1} \pm \text{SD}$)	42 ± 6	50 ± 8	38 ± 7	34 ± 4
Vo_2 at VAT ($\text{mL} \cdot \text{kg} \cdot \text{min}^{-1} \pm \text{SD}$)	26 ± 5	27 ± 6	23 ± 4	19 ± 3
Vo_2 at VAT/Max Vo_2 (%)	54 ± 6	55 ± 10	61 ± 7	58 ± 8

VAT, ventilatory anaerobic threshold; Vo_2 , minute oxygen consumption.

J Appl Physiol 1984;56:628–634.

loads, and to establish levels of exertion for programmes of exercise fitness. Serial measurement is probably a better indicator of changes in aerobic fitness than maximal consumption of oxygen.

Cardiac Output

Noninvasive measurement of cardiac output is an important adjunct to the assessment of aerobic capacity. In children with diminished ability to increase cardiac output, working capacity and aerobic capacity can be preserved by several mechanisms. Exercising muscles can extract a higher percentage of delivered oxygen, widening the arterio-venous gradient of oxygen. A higher amount of work can also be performed anaerobically. Assessment of the increase in cardiac output with exercise may identify these compensatory mechanisms.

Data on the response of cardiac output in healthy children is less available than that on aerobic capacity. Most healthy children increase resting cardiac output approximately four-fold during progressive exercise. The maximal cardiac output with exercise is less in preadolescents compared with adolescents and adults when normalised for body surface area,^{30,38} primarily because of lower stroke volume. Noninvasive measurement of cardiac output is one of the less reliable measurements routinely made in a paediatric exercise laboratory. Variations of at least one-tenth from test to test have been found in individual subjects.³⁸ The reasons for such variation are multiple, and reflect inherent inaccuracies in the methodology, technical difficulties, and variation from test to test within individual patients. Normal values for exercise cardiac output are presented in Table 20-6.

Pulmonary Function

Measurements of pulmonary function with exercise are often abnormal in children with structural heart defects.^{60,61,64,65} The causes of these abnormalities are not entirely clear, but are probably multi-factorial. Defects involving abnormalities of the pulmonary vasculature, such as seen in patients with tetralogy of Fallot, appear to be more commonly observed. In these patients, a restrictive pattern of breathing, with decreased forced vital capacity and tidal volume, is commonly observed on resting spirometry.⁶⁰ This results in a higher frequency of breathing during exercise in order to maintain adequate minute ventilation. Obstructive patterns occur less frequently. Multiple thoracotomies resulting in formation of

scar tissue may be one cause of these findings. These patterns have also been observed in children who have had a single surgical intervention.⁶⁰ Residual lesions, such as significant pulmonary regurgitation, appear to be associated with increased ventilatory abnormalities. In some cases, there is evidence that developmental abnormalities of the airway may be an intrinsic part of this particular cardiac abnormality.^{60,65}

There are age-related changes that should be considered in the assessment of the patterns of ventilation of children and adolescents. Younger children normally have more inefficient patterns, with lower tidal volumes and higher frequencies of breathing than adolescents and adults.⁶⁶ This inefficiency results in a higher ratio of physiological dead space to tidal volume, and should not be misinterpreted as evidence of a pulmonary abnormality. Most pulmonary abnormalities do not limit exercise performance in children with congenitally malformed hearts. In many cases, the pulmonary abnormalities are relatively mild, and the exercising subject compensates by changing the pattern of breathing. Also, many children with congenitally malformed hearts have impairment in their cardiovascular system that limits their exercise capacity before decreased pulmonary reserve becomes a factor in exercise performance. Occasionally, a child is limited by pulmonary performance. Treatment directed at improving their pulmonary function may then result in improved exercise performance.

Response of Blood Pressure

Systolic blood pressure rises during exercise. Diastolic blood pressure generally falls, or is unchanged. Age, gender, and racial differences in blood pressure are found in the general population. Using appropriate normal values is essential, therefore, when assessing the response of blood pressure response. As a general rule, it is uncommon for systolic blood pressure to exceed 200 mm Hg in healthy children. In the evaluation of children with suspected hypertension and a structurally normal heart, systolic blood pressure in excess of 250 mm Hg is usually grounds for terminating the test.³⁰

Abnormal responses during exercise are seen with certain cardiac lesions. A blunted rise or fall in systolic blood pressure may indicate severe obstruction of the left ventricular outflow tract, or pulmonary hypertension.³⁰ Elevated systolic blood pressures have been observed with residual coarctation of the aorta, and with abnormalities of the sympathetic-adrenal axis following successful repair of coarctation.^{56,67}

Electrocardiographic Data

Complete electrocardiographic data is routinely obtained during testing of patients with structural cardiac disease. Evidence of chronotropic impairment, exercise-induced arrhythmias, and changes suggestive of myocardial ischaemia, are also routinely assessed. We will discuss the latter in more detail in the subsequent section. Impairment of the response of the heart rate to exercise limits augmentation of cardiac output. Chronotropic impairment is common after surgical repairs such as the atrial switch and Fontan operations^{61,63} as well as following surgical repair of tetralogy of Fallot.⁶⁰ Often, it is difficult to determine the effect

TABLE 20-6

CARDIAC OUTPUT WITH EXERCISE

Age	Resting Cardiac Index	Maximal Cardiac Index
11–13 years	3.9 L/min/m ²	12.5 L/min/m ²
13–14 years	5.25 L/min/m ²	17.4 L/min/m ²

Adapted from Eriksson BO, Koch G: Cardiac output and intraarterial blood pressure at rest and during submaximal and maximal exercise in 11–13 year old boys before and after physical training. In Bar-Or O, Natanya I (eds): *Paediatric Work Physiology*. Netanya, Israel: Wingate Institute, 1973, pp 139–150; and Eriksson BO, Grimby G, Saltin B: Cardiac output and arterial blood gasses during exercise in pubertal boys. *J Appl Physiol* 1971;31:348–352.

that mild chronotropic impairment will have on aerobic performance. Marked impairment invariably results in decreased aerobic capacity.

Evaluations of arrhythmias include identification of the source, be it supraventricular or ventricular, and the response of the disturbance to increasing exercise effort. The occurrence of new or potentially malignant arrhythmias, such as premature ventricular depolarisations that degenerate into ventricular tachycardia during exercise, is part of the stratification of risk that should be offered by the exercise physiology laboratory.⁶⁸ Changes in the QRS complex, such as when the morphology during ventricular pre-excitation is replaced with antegrade atrioventricular nodal conduction, or changes in the QTc duration in individuals at risk, are also routinely assessed.

Evaluation of pacing includes assessment of proper function at rest, during exercise, and recovery. The electrocardiographic recording should be assessed to show that sensing and pacing are appropriate to the settings. A recent interrogation and confirmation of the settings prior to the test are helpful to the exercise physiology laboratory staff. The type of exercise protocol used may be important to such testing. Rate responsive pacemakers, which have motion detecting piezoelectric crystals, usually require a treadmill protocol in order to provide sufficient motion for a normal response of rate.^{69,70} Evaluation of a rate responsive pacemaker includes assessment of the maximal heart rate, as well as the slope of the rise in heart rate versus rate of work. A slope that is too shallow or steep may impair cardiac output and aerobic capacity. Measurement of aerobic capacity becomes useful in the evaluation of pacemaker settings, especially rate responsive models. The effects of changes in settings can be more easily evaluated by serial assessment of aerobic capacity.

Evaluation of Myocardial Ischaemia

Traditional assessment for possible coronary arterial insufficiency has centered upon the classic signs and symptoms of myocardial ischaemia, such as chest discomfort and electrocardiographic changes. Unfortunately, many children with coronary arterial insufficiency do not experience the classic symptom of crushing sternal chest pain. Furthermore, coronary arterial insufficiency which occurs in a controlled setting, such as in the exercise physiology laboratory, may not be accompanied by changes in the ST segments. Most of the previously published literature regarding exercise-induced myocardial ischaemia in children is based on the assumption that the indicators of myocardial perfusion, namely electrocardiographic changes or nuclear perfusion abnormalities, are similar to those seen in adults. This may not be a valid assumption. Fortunately, significant advancements in medical diagnostics have provided the clinician with alternative methods for detecting subclinical coronary arterial insufficiency.

Electrocardiographic Changes

The electrocardiogram is the initial diagnostic tool in the evaluation of possible coronary arterial insufficiency. Dysfunctional or ischaemic myocardium depolarises abnormally, and therefore will repolarise abnormally. It is this

characteristic of abnormal repolarisation which was first recognised and documented in 1918, when Guy Bousfield noted depression of the ST segments during a spontaneous anginal attack in an adult who had a history of syphilis and clinically had aortic insufficiency.⁷¹ Electrocardiographic criteria for ischaemia in children have been extrapolated from changes noted in adults. Horizontal or downward depression of 1 mm or more for greater than 60 to 80 msec has been universally accepted as that criterion which suggests myocardial ischaemia. Historically, such changes have been observed in many disorders that are characterised as having either abnormal coronary vasculature, or increased myocardial demands for oxygen (Table 20-7). There remains controversy regarding the most accurate assessment of depression of the ST segments.³¹ The two common methods for measuring changes on raw data, the PR isoelectric method and the PQ-PQ isoelectric method, are shown in Figure 20-12. Although the PQ-PQ isoelectric method is easier, assuming a flat baseline, it has a higher incidence of false positive values in healthy children.³¹ With current technology, signal averaging is superior to either technique (see Fig. 25-12).

Studies of patients with congenitally malformed hearts in which coronary arterial insufficiency was assessed electrocardiographically have primarily focussed on abnormalities of the coronary arteries. Such lesions include anomalous origins or courses of the coronary arteries, coronary vasculitides such as seen in Kawasaki syndrome, and surgically reimplanted coronary arteries as encountered after the arterial switch procedure and the Ross operation.^{46,54,72,73}

Neither the sensitivity nor specificity of the changes compares favourably with other tests of myocardial perfusion in children. ST segment changes and nuclear perfusion imaging have correlated poorly in such conditions as anomalous origin of the left coronary artery from the pulmonary trunk, Kawasaki disease, and after the arterial switch procedure.⁴⁴⁻⁴⁶ Correlation with the severity of obstruction in left-sided obstructive lesions such as valvar aortic stenosis is somewhat better.⁵⁴ Correlation is poorer, nonetheless, following surgical repair of these lesions.

TABLE 20-7

DIAGNOSES ASSOCIATED WITH ST SEGMENT CHANGES DURING EXERCISE

Aortic stenosis
Anomalous left coronary artery from the pulmonary artery (ALCAPA)
Anomalous origin of a coronary artery from the opposite facing sinus of Valsalva
Kawasaki syndrome
TGA, arterial switch operation
Hypertrophic cardiomyopathy
Heart transplantation
Thromboembolic disease
Mucopolysaccharidoses
Coronary vasculitides
Systemic hypertension
Drug ingestions (e.g., cocaine)
Hyperlipidemias with premature atherosclerosis

Both methods are sensitive to artifact and baseline drift. **B**, Composite QRS beats obtained by signal averaging. The computer inserts markers at the point of initial deflection of the QRS, the J point, and 40 msec after the J point. (Top panels, reprinted with permission from Bricker JT. Pediatric exercise electrocardiography. In Rowland TW (ed): Pediatric Laboratory Exercise Testing: Clinical Guidelines. Champaign, IL: Human Kinetics Publishers, 1993.)

A number of conditions will produce a false positive test, including hyperventilation, digoxin therapy, antidepressants, oestrogen therapy, hypokalaemia, mitral valvar prolapse, or stove chest. False negative tests are also common as previously mentioned, easily comprehensible given that the

changes appears to be a relatively late finding in the evolution of the ischaemic process (Fig. 20-13). Furthermore, the magnitude of the change does not always correlate with the severity of the disease. Although historically used in adults, therefore, the electrocardiogram does not appear to be the

Figure 20-13 The evolution of the ischaemic process and the clinically applicable tests. (Reproduced with permission from Kimball TR: Pediatric stress echocardiography. *Pediatr Cardiol* 2002; 23:347–357.)

most accurate test for detecting coronary arterial insufficiency in children. Alternative methods are commonly used.

Nuclear Perfusion Imaging

Myocardial perfusion imaging has been used extensively in the assessment of myocardial ischaemia, infarction, and viability in congenital and acquired cardiac disease. Such studies are performed by injecting a radioisotope, which is a relatively unstable element that emits photons and is bound into functioning cardiac myocytes. The receptive myocytes emit a signal which can be captured by a gamma scintillation camera and processed with digital computer systems. Utilising a series of rotating head cameras that can acquire images in multi-plane slices, it is possible to generate a tomogram of the photon-emitting myocardial tissue; hence the name single photon emission computed tomography. The magnitude of the uptake of the isotope correlates with the thickness of the tissue, so that the right ventricle is not typically imaged with this modality unless there is significant hypertrophy, such as in severe pulmonary stenosis or a systemic right ventricle.⁷⁴ Injured, diseased, or dead myocardial cells do not readily take up the radioisotope, resulting in a perfusion defect on resting and/or stress images (Fig. 20-14). Typical protocols utilise studies at rest and after stress-imaging done on the same day, allotting enough time between the sessions to allow washout of the radioisotope. Comparison between the sets of images allows qualitative assessment of relative decreased perfusion in regions of the myocardium.

Two isotopes are commonly used in children. The tracer thallium-201 was once commonly used in most major paediatric centers, but has given way to technetium, a radioactive product of uranium decay. Thallium has the advantage of rapid clearance, allowing for less time between resting images and images acquired at peak exercise. Its rates of washout, however, have been quite variable in children.⁷⁵

Furthermore, there is a relatively high incidence of false positives with thallium during pharmacological testing in adults with coronary arterial disease.⁷⁶ Technetium 99m has several advantages over thallium, principally its improved radiation dosimetry, producing less gonadal absorption.⁷⁵ The disadvantage with technetium is the low hepatic clearance. Because of this, it is necessary to wait at least one hour to avoid marked hepatic activity, which can obscure results. Technetium linked to methoxy-isobutyl-isonitrile is employed in many centers.

The diagnostic accuracy of such imaging has been studied to a limited extent in patients with Kawasaki disease.⁷⁷ The sensitivity of myocardial perfusion imaging in this disorder has been good, ranging from 70% to 90%. The specificity, however, has been limited. Imaging has also been valuable in stratification of risk, as the presence of reversible defects during stress testing has been predictive of future cardiac events.⁷⁸

The technique has also been used in patients after a successful arterial switch procedure.^{44,77,80} Perfusion abnormalities appear to be common in such patients, although the correlation between perfusion defects and clinical outcome has yet to be determined.

Positron Emission Tomography

Positrons are positively charged subatomic particles, generated with the use of a medical cyclotron. Commonly employed elements such as oxygen, nitrogen, and rubidium are made unstable in medical cyclotrons, producing very short lived isotopes that are safe for medical use. When injected into the targeted tissue, the positrons from these elements combine with the electrons in surrounding tissue and annihilate each other. This annihilation reaction emits gamma ray photons, which are visible and therefore recordable with tomographic equipment. These tracers are excellent choices for myocardial blood flow studies.

Figure 20-14 Preoperative images obtained using single photon emission computed tomography (SPECT) in an 8-year-old with anomalous origin of the right coronary from the left facing aortic coronary sinus. Note the reversible, inferior basal perfusion defect shown in the top right frames at 8 o'clock.

Advantages of this form of imaging include higher count rates, better image quality, superior attenuation correction algorithms, and greater ability to quantify myocardial flow of blood and flow reserve.⁸¹ Its disadvantages are that the tracers are very unstable, and must be used immediately, often requiring an on-site cyclotron which increases the cost relative to imaging based on single photon emission computed tomography.

Because of the extremely short half-life of the positron-emitting isotopes, exercise testing is impractical, resulting in pharmacological stress testing as the preferred method for studies using positron emission tomography. These studies are usually performed while the patient is in the scanner in order to allow for immediate acquisition of images following completion of the protocol for intravenous infusion of the drug. The short half-life of the isotope limits the utility of imaging in circumstances where additional data regarding exercise performance such as maximal consumption of oxygen or working capacity is desired.

Despite these limitations, the technique has significant advantages over the alternative technique using single photons. Lower radiation doses of emitted photons compared to single photons permits its use in research studies on healthy adults. In addition, technology allows for quantification of regional myocardial flow of blood, resulting in absolute flows at rest and stress for all myocardial regions, and computation of coronary arterial flow reserve, this being the ratio of peak over resting flows. Studies of patients with congenitally malformed hearts utilising positron emission technology have focused on lesions in which manipulation of a coronary artery was part of the surgical repair, including the arterial switch operation and aortic valvar disease. Investigators found perfusion defects in one-third of patients when compared to controls,⁸² a finding confirmed by others, albeit with the second group finding no perfusion defects in patients undergoing the Ross

operation.⁸³ Children have also been studied with acquired coronary arterial disease, typically due to Kawasaki disease, such patients having diminished flow reserves compared to normal subjects.⁸⁴⁻⁸⁷ All of these studies have compared regional flow to data obtained from young healthy adults. Even with extremely low-dose radiation, it has not been ethically feasible to collect data on regional myocardial blood flow in healthy children and adolescents using positron emission technology. The assumption in current studies is that the myocardial response to pharmacological vasodilation and coronary arterial flow reserve are similar in children compared to young adults. Given the lack of reliable data to substantiate this assumption, literature reporting the coronary arterial flow reserve in children must be interpreted cautiously.

Reports of exercise testing in patients with both Kawasaki disease and after the arterial switch procedure have found that a significant number of exercise-induced defects are not associated with either symptoms of ischaemia or electrocardiographic changes.^{44,45} Similar findings have been reported for anomalous origin of the left coronary artery from the pulmonary trunk.⁴⁶ The reason for these discordant findings is unclear. It is possible that these perfusion defects are false positive findings caused by photon attenuation from overlying tissue. Unlike in adults, there are no normal standards to correct for attenuation in children. Lack of demonstrable lesions in the coronary arteries by cardiac catheterisation or echocardiography would support this hypothesis. Another possibility is that these defects represent microvascular disease. The latter explanation is congruent with the proposed ischaemic cascade (see Fig. 20-13), in which electrocardiographic changes and symptoms of ischaemia are relatively late findings. This may suggest a fundamentally different electrocardiographic and symptomatic response to sub-endocardial ischaemia in children compared with adults. Currently, the significance of exercise-induced myocardial

perfusion defects observed on nuclear imaging in children remains uncertain for many lesions.

Stress Echocardiography

Kraunz and Kennedy were the first to report on mural motion after exercise using echocardiography,⁸⁸ with Berthe and colleagues⁸⁹ then describing dobutamine stress of the myocardium as assessed by echocardiography.⁸⁹ This technique has since been used in attempts to improve on changes in the ST segments alone in the assessment of exercise-induced myocardial ischaemia in certain congenital cardiac lesions.⁹⁰ In situations where the cardiovascular anatomy has been essentially restored, such as after the arterial switch procedure or repair of anomalous origin of the coronary arteries, the technique allows for the assessment of regional left ventricular wall motion both at rest and during exercise, using the same criteria established for adults with coronary arterial disease. The approach uses standardised echocardiographic views before and after stress, providing the stress either using a treadmill or cycle ergometer, or by employing pharmacological agents, such as dobutamine, adenosine, or dipyridamole. Dobutamine mimics exercise by increasing heart rate and blood pressure, while adenosine causes vasodilation of the normal coronary vasculature, which steals from the diseased segments, revealing subsequent abnormalities of mural motion. Dipyridamole inhibits cyclic nucleotide phosphodiesterase, and inhibits uptake of adenosine. Wall motion is analysed either globally or by grading 16 myocardial segments.⁹¹ Ischaemia is manifest as either new or worsened abnormalities of motion.

There are limitations when utilising stress echocardiography that are unique to patients with congenitally malformed hearts. In those with complex defects, or those with artificial material such as patches or baffles, unusual ventricular anatomy such as a systemic morphologically right ventricle creates problems unusual ventricular anatomy such as a systemic morphologically right ventricle, in the assessment of changes in mural motion. Many postoperative patients have varying degrees of electrocardiographic abnormalities of conduction, which can also make analysis difficult, both at rest and during exercise. In patients with congenital cardiac lesions, it can also be difficult to measure mural motion immediately after exercise. Often, this is related to poor acoustical windows after surgery, and the high respiratory rates typically seen in young patients. High respiratory rate results in more lung interference, which often impairs imaging. Lack of cooperation in very young patients may also be an impediment to obtaining clear images. These problems have led to the use of pharmacological stress testing in certain subgroups of patients when performing stress echocardiography.

Pharmacological stress echocardiography, therefore, has gained favour for use in children for a variety of reasons, including the technical difficulties in providing maximal exercise. The available pharmacological agents, as discussed above, are those that increase myocardial consumption of oxygen, such as dobutamine and isoproterenol, and those that cause coronary vasodilation, such as adenosine and dipyridamole.⁹⁰ The choice of the agent to be used is based on the type of defect and the reason for the study. Coronary vasodilators are usually chosen when a stenotic coronary lesion is suspected.

Dobutamine, possessing both positive chronotropic and inotropic properties, is the most frequently used agent. In the typical test, the resting images are obtained for baseline comparison. Dobutamine is then infused usually at an initial dose of 5 µg/kg/min. The dose is then increased at a fixed time interval, often 3 minutes, to either a predetermined maximal level or until the development of symptoms. Assessment of changes in mural motion are usually made at the completion of each dosing increment.

The technique has been now been validated as an accurate diagnostic tool in patients with Kawasaki disease.⁹² It has also been found to be congruent with myocardial perfusion imaging in patients after the arterial switch operation.^{93–95} These studies show that stress echocardiography offers good sensitivity and specificity. Its predictive value in children, nonetheless, remains to be seen.

CONTRAINDICATIONS AND REASONS TO TERMINATE EXERCISE TESTS

Contraindications

There are both absolute and relative reasons not to perform exercise testing. Many of these reasons are listed in Table 20-8. As a rule, absolute contraindications result from an acute ongoing process affecting one or more of the major organ systems, such as myocarditis or hepatitis.^{27,30}

Relative contraindications require that the physician supervising the laboratory evaluate the relative risk and benefit for exercise testing for that particular patient.^{27,30} Occasionally, a relatively high risk during exercise testing may be acceptable. For example, routine exercise testing in patients with advanced pulmonary vascular obstructive disease is not appropriate because of the high risk of exercise-induced sudden death. Exercise testing, nonetheless, may be warranted as part of an evaluation to make a difficult decision concerning the timing of lung or heart-lung transplantation.

TABLE 20-8

CONTRAINDICATIONS TO EXERCISE TESTING

Absolute

1. Active inflammatory heart disease
2. Active hepatitis
3. Acute myocardial infarction
4. Active pneumonia
5. Severe systemic hypertension for age
6. Acute orthopedic injury to an exercise muscle group

Relative

1. Severe left ventricular outflow obstruction
2. Severe right ventricular outflow obstruction
3. Congestive heart failure
4. Pulmonary vascular obstructive disease
5. Severe mitral stenosis
6. Ischemic coronary artery disease
7. Advanced ventricular arrhythmias

Reasons to Terminate an Exercise Test

There are at least four reasons to terminate an exercise test:

- The patient requests termination.
- The diagnostic criterions for performing the exercise test have been met.
- The monitoring equipment has failed and could compromise safety.
- Signs or symptoms are present that suggest the patient could be at significant risk if exercise continues.

Judging the level of fatigue of the patient using a perceived exertion scale, such as the Borg scale, is useful in anticipating when a patient is likely to refuse further exercise. Onset of dizziness, erratic respiratory patterns, or chest pain frequently indicates potential abnormalities requiring termination of testing. A significant fall in systolic blood pressure may indicate inadequate cardiac output. Likewise, an excessive rise in blood pressure greater than 250 mm Hg may be considered reason to terminate a test, although there is no evidence of significant increase in risk in an asymptomatic child who has a structurally normal heart.³⁰ ST segment depression of greater than 3 mm should be observed to indicate significant ventricular ischaemia, and is an indication for termination. Increasing frequency of arrhythmias, or exercise-induced atrioventricular block, will often require termination, but should be judged on an individual basis. Reasons for termination are summarised in Table 20-9. Careful preparation and monitoring are essential to successful testing. If adequate attention is given to appropriate preparation and monitoring, it is unusual that an exercise test will need to be terminated before achieving the diagnostic goals.

CONDITIONS WHERE EXERCISE TESTING IS OF VALUE**Congenital Cardiac Disease**

More formal exercise studies have been performed in children with congenitally malformed hearts than any other group of children. Exercise testing in such patients can aid

the decision-making process as to whether an intervention such as surgery is needed or can help in assessing the success of a previously performed intervention.

Unrepaired Congenital Cardiac Lesions

Left-sided obstructive lesions, including aortic stenosis, have been the subject of numerous studies, and are common reasons for referral of the patient for stress testing. The exercise test should evaluate for the presence of subendocardial ischaemia. A blunted rise in systolic blood pressure may occur in severe cases. Results of exercise testing alone are seldom a definitive reason for surgical intervention, but may be useful as part of an overall assessment of the severity of obstruction.

Surgically Repaired Congenital Cardiac Disease**Transposition**

Atrial redirection operations were widely used during the 1960s and 1970s, with identified later sequels of atrial arrhythmias, diminished right heart function, chronotropic impairment, and reduced exercise performance.⁶³ Improvements in surgical technique and post-surgical management resulted in advent of the arterial switch operation in the late 1970s, still employed as the procedure of choice at the time of this writing. Both physical working and aerobic capacities are clearly superior in patients after an arterial compared to an atrial switch.^{63,96} Patients who have undergone the arterial switch operation as a group have normal consumption of oxygen, and maximal cardiac indexes compared to healthy subjects, which is not the case with patients after atrial redirection.⁷² The potential late-term sequels of reimplanted coronary arteries remain to be seen. Published studies to date indicate an incidence of approximately 10% in exercise-induced ischaemic changes in patients after an arterial switch.⁷² Studies of myocardial perfusion imaging in this population were discussed above.

Tetralogy of Fallot

Most studies of exercise performance before 1990 in patients after surgical repair of tetralogy of Fallot found mild-to-moderate reduction of aerobic capacity compared to healthy controls.^{65,97–104} More recently, a study found near normal physical working and aerobic capacities.¹⁰⁵ The presence of free pulmonary insufficiency and right ventricular dilation appear to be key factors in limiting aerobic capacity in this population.

Repair of Anomalous Coronary Arteries

No significant differences were found in rate of work or consumption of oxygen in patients with anomalous left coronary artery from the pulmonary trunk when repair was performed at less than 2 years of age compared to those repaired beyond infancy,⁴⁶ albeit that the clinical significance of these findings remains to be seen.⁴⁶

Fontan Physiology

Several studies have shown that patients with the Fontan circulation uniformly have diminished physical working and aerobic capacities, chronotropic impairment, reduced stroke volume, intracardiac and intrapulmonary shunting, and abnormal pulmonary mechanics.^{106–112} Important work in the field of exercise physiology has helped to influence the timing of surgical intervention. A decade ago, it was common for the Fontan procedure to be

delayed until age 3 or 4 years or beyond. Following work at a number of institutions, showing that exercise capacity is higher when the systemic ventricle is volume unloaded at an earlier age,^{113,114} it is now common to perform an intermediate procedure, such as a bidirectional Glenn anastomosis, within the first year of life, then complete the Fontan circuit by 2 or 3 years of age. Heart rate responses are often impaired in patients with the Fontan circulation, and rate responsive pacemakers have been implanted in order to make the response during exercise as close to normal physiology as possible, albeit that physical working and aerobic capacities do not always improve significantly.^{70,115} This contrasts with results for patients with failing Fontan physiology, who demonstrate improvement in nearly all indexes of exercise performance.^{113–118}

Coarctation of the Aorta

Residual coarctation is commonly observed in patients after repair of coarctation. Previous studies demonstrated that a significant residual coarctation may be unmasked during exercise testing when systolic hypertension occurs during exercise. Other investigators found significant residual lesions noted at cardiac catheterisation when the exercise study prior to the catheterisation uncovered an elevated systolic gradient between the limbs during recovery. The presence of augmented sympathetic nervous system and renal responses to exercise may contribute to the development of chronic hypertension in patients with this condition.⁶⁷

Totally Anomalous Pulmonary Venous Connection

There is very little data regarding exercise performance in patients after repair of this lesion. Those with no residual anomalies have mildly reduced aerobic capacity, along with mild chronotropic impairment. Mild restrictive mechanics on formal pulmonary function testing has also been noted, but these do not appear to impact on performance.^{64,119}

Acquired Disease

Kawasaki Syndrome

The impact that Kawasaki syndrome has on the coronary vascular bed has been the subject of much work, anticipating that this childhood illness may have late-term effect (see also Chapter 52). We routinely perform exercise studies on patients long after the acute illness has resolved in order to help with assessment of risk.¹²⁰ Others using quantitative analysis with positron emission tomography have shown that patients with Kawasaki disease without echocardiographic evidence of coronary arterial abnormalities had abnormal responses to adenosine stress testing, with evidence of reduced myocardial blood flows, reduced myocardial blood flow reserve, and higher total coronary resistance.⁸⁵ Despite these abnormal laboratory findings, maximal consumption of oxygen is normal, regardless of the state of the coronary arteries.⁴⁵

Arrhythmias

It has been observed in patients with long QT syndrome that the QTc interval may prolong during intense work, and potentially lead to life-threatening arrhythmias. A formal exercise test, therefore, may be useful in excluding the syndrome in selected patients. We have found that exercise testing, although not always diagnostic, can be helpful

when attempting to stratify risk. The morphology of the T wave at rest, during exercise and recovery, may also be of diagnostic value.¹²¹

Recipients after Heart Transplantation

Exercise performance is impaired following orthotopic heart transplantation compared to otherwise healthy peers.^{122–124} Several factors are thought to be involved, including chronotropic impairment, musculoskeletal abnormalities, and abnormalities in systolic and diastolic function.^{125–127} Studies of supervised programmes of rehabilitation have shown initial improvement, but subsequent decrease in exercise performance.^{122,129} These findings suggest that exercise testing may be an additional useful non-invasive marker of early dysfunction of the graft, and if followed serially, exercise testing may serve to alert clinicians to modify the treatment and management of children subsequent to cardiac transplantation. Myocardial perfusion imaging and stress echocardiography could also be useful in evaluating the coronary arteries and abnormalities in mural motion, factors which may also contribute to progressive deterioration in exercise performance.

Non-Cardiac Illnesses

Survivors of Childhood Cancers

Anthracycline-induced cardiomyopathy, seen in children who survive childhood cancers, causes a reduction in physical working and aerobic capacities.¹³⁰ In this group of patients, working rate may improve with time, although afterload reduction did not alter the indexes of exercise performance.¹³¹

Systemic Hypertension

Differences in gender and race are found in responses of blood pressure to treadmill testing in healthy children.^{132–134} The implication of these findings is not clear.^{134,135} In most studies, systolic blood pressure rarely exceeds 240 mm Hg. These publications contain tables and figures that assist in assessing an abnormal response to graded exercise. We do not terminate testing unless the systolic blood pressure exceeds 250 mm Hg.

Most exercise physiologists agree that, despite the occurrence of systolic hypertension during exercise, there are beneficial effects of regular aerobic exercise toward lowering resting blood pressures.^{1,136} There are no large studies to suggest that regular exercise is harmful to hypertensive youth. Regular exercise, therefore, should be part of the therapeutic regimen for hypertensive youth.

Exercise-Induced Asthma

Asthma and suspected exercise-induced asthma is a common reason for referral for exercise testing. The possible mechanisms by which exercise induces asthma are both physical, such as cooling and drying of the airways, and chemical, such as metabolic acidosis, these triggers initiating an abnormal physiological response which affects the bronchial smooth muscle. Complete reviews of these mechanisms are available elsewhere.^{137,138}

Exercise-induced asthma occurs in up to nine-tenths of patients with persistent asthma, and in about one-tenth of the general population.¹³⁹ This condition is defined as 'transient narrowing of the airway that follows vigorous exercise'.¹⁴⁰ In healthy individuals, there is a fall of no more than 5% in forced expiratory volume in 1 second with

exercise, but in exercise-induced asthma, the fall is between 10% and 25%.^{137–143} Most clinicians consider a drop of 15% as diagnostic. The deterioration in lung function typically manifests as cough, shortness of breath, wheeze, chest pain/tightness, or inability to perform at physical activities and exercise.¹³⁹ Our protocol, which consists of rapidly increasing treadmill speed and grade such that the patient is running near their maximal capacity for approximately 6 to 8 minutes, is designed to provoke bronchospasm in pre-disposed subjects. Treadmill or free running is the preferred modality because it increases the time spent at high minute ventilation, thus decreasing the refractory time for potential bronchospasm. These features are not appreciated when using a graded or ramp protocol. Pre- and post-pulmonary function studies, and flow-volume loops obtained during the study, are analysed by pulmonologists working jointly with cardiologists. Significant exercise-provoked deterioration in pulmonary function is treated with bronchodilators, and pulmonary function studies are repeated. After appropriate treatment, children with exercise-induced asthma should be able to participate in sports and maintain normal activity.¹³⁹

Cystic Fibrosis

This is a progressive disease that occurs in approximately 1 of every 1700 live Caucasian births. The primary organs involved in this disease, which is non-curable, are the lungs, pancreas, sweat glands, and intestinal mucosa. Striking heterogeneity in the presentation, clinical course, and prognosis of individuals with cystic fibrosis has been noted for decades.¹⁴⁴ Survival has now increased significantly, with many individuals living well into their fourth decade of life as a result of advances in medical therapy.¹⁴⁵

Exercise capacity is directly related to the degree of pulmonary dysfunction, and is of prognostic value.¹⁴⁶ Patients are often under-nourished, which may affect the function of skeletal and respiratory muscles,¹⁴⁷ and portends higher mortality.¹⁴⁸ Published data has demonstrated low physical working and aerobic capacities, as well as low pulmonary reserves.^{144,150} Unpublished data from our laboratory has confirmed the suspicion that there is a positive correlation between lean body mass, pulmonary function, and exercise performance. We surmise that actively supervised programmes for physical rehabilitation, and improved nutritional support, will likely be an integral part of a comprehensive approach to fostering a normal quality of life for these individuals.

This scientific statement from the American Heart Association describes the role of exercise testing in the evaluation of children and adolescents with known or suspected cardiovascular diseases. Included are the minimum training requirements for the exercise physiology laboratory staff, as well as a primer on accurate interpretation of tests based upon size and age-appropriate normal data.

- Cooper DM, Weiler-Ravell D, Whipp BJ, Wasserman K: Aerobic parameters of exercise as a function of body size during growth in children. *J Appl Physiol Respirat Environ Exerc Physiol* 1984;56:628–634.

This research study examined metabolic and respiratory data during cycle exercise as a function of the changes in body weight during growth in 109 healthy children using ramp cycle ergometry. Results indicate that work efficiency and the mean response time for consumption of oxygen each minute are independent of age and size, but increased in a higher ordered manner with increasing size, and the onset of anaerobic metabolism during exercise occurs at a relatively constant proportion of the overall limit of gas exchange.

This study evaluated the exercise responses of 42 patients with Fontan physiology to that of 28 age-matched controls during supine cycle ergometry. Results indicated that impairment in ventricular filling is more predictive of exercise performance than the heart rate responses.

- Davis JA, McBride MG, Chrisant MA, et al: Longitudinal assessment of cardiovascular exercise performance after paediatric heart transplantation. *J Heart Lung Transplant* 2006;25:626–633.

Serial longitudinal exercise performance was evaluated in 28 children following cardiac transplantation. Results indicated that exercise performance is impaired, and despite an initial improvement, declines over time. The deterioration in exercise performance correlated with increasing diastolic dysfunction, a finding also frequently cited in adult studies in this population of patients.

Description and Analysis of Data, and Critical Appraisal of the Literature

BRIAN W. McCRINDLE

The current standard of practise when faced with a clinical dilemma is to make decisions based on the use of evidence. This is broadly defined as decision-making that incorporates the best available research, together with clinical judgement, while considering also the preferences of the patient, or his or her parents. Thus, evidence based on research is brought to bear on individual and specific circumstances. Evidence based on research implies the use of data or measurements acquired in order to test a hypothesis concerning an area of uncertainty. The data itself may have been initially collected for reasons other than research, as is the case with data acquired from administrative, medical record, or observational sources, or to address specifically a research question, such as with prospective studies or clinical trials. The circumstances under which the data were collected, including their purpose, degree of measurement, rigour, and design of the study, play an important role in influencing the degree to which any conclusions or extrapolations from that data are valid or reflect the truth, in other words, whether they are free from systematic error and bias, are reliable, being free from random error, and apply to the clinical situation at hand. Data must be clearly described, relationships must be accurately and reliably determined, and the report must have sufficient detail to allow complete critical appraisal. The evaluation of presented data and analyses is a key skill for the contemporary clinician faced with increasingly complex clinical situations, and an exponentially expanding body of available literature.

MEASUREMENT AND DESCRIPTION OF DATA

Level of Measurement

Data is specific pieces of information that are defined by their level of measurement and their relationship to other data. Those pieces of information are often referred to as variables, since they may take on different values. The type of values that a variable may assume determines the level of measurement. The level of measurement determines how the values for a given variable are to be described, and how associations between variables are to be assessed and related to random error or variations. Levels of measurement can be categorical, ordinal, ratio, and interval.

Categorical variables are those for which the values fall into discrete and mutually exclusive categories. The value for a given individual or measurement can be applied to only one category. The relationship between the different

categories reflects a qualitative difference. Variables with only two categories are referred to as being dichotomous or binary. Examples of dichotomous categories include yes or no, present or absent, male as opposed to female, and right versus left. Examples of variables with more than two categories include the type of connection used to create the Fontan circulation, the position of a ventricular septal defect, and medications used.

When presenting measurements related to a categorical variable, the frequency can be given either as the absolute number of measurements within that category, or as a proportion or percentage of the measurements from all of the categories. It is important to be clear about the denominator when giving percentages, and not to provide decimal places for percentages unless they will have meaning or importance. Giving the denominator is also important, since often the values for some individual measurements may be either missing, either because they were not measured or are not available, or else not applicable, in that the variable may not apply to that individual, such as the presence of amenorrhea in male subjects. The denominator should represent only those with non-missing and applicable values. The number of missing and inapplicable values should be reported separately. Alternatively, the number of non-missing and applicable values should be given. For example, 'Of 38 patients converted to the Fontan circulation, 21 (55%) were male, and chromosomal abnormalities were present in 4 (8%) of the 48 subjects tested'. For some categorical variables, an individual may have multiple values that place him or her in more than one category. A patient may be taking more than one medication. For this situation, there are two approaches. First, a category for that variable could include a specific combination of categories. For example, 'At most recent follow-up, 19 (50%) of the 38 patients with the Fontan circulation were taking anticoagulant medication, including warfarin alone in 10, aspirin alone in 8, and one patient taking both'. Second, the variable could be split into multiple categorical variables reflecting each category. In this example, the sentence would be, 'Warfarin was used in 11 patients and aspirin in 9 patients, with one patient taking both'.

A specific type of dichotomous categorical variable is the occurrence of a discrete event, such as performance of an intervention, or death. Events are almost always associated with an interval reflecting a period of time at which the risk exists. That period of time is an important aspect of that

particular variable. This can be presented as the number of patients experiencing the particular event during a specified period expressed as a proportion of patients at risk for that event. For example, 'There were 5 (13%) deaths within 30 days of surgical completion, in 38 patients, of the Fontan circulation'. A frequent problem, however, is that not all individuals will have the same period of risk, given that some patients will be lost to follow-up, or something will happen, usually another event, which will cause them no longer to be at risk. The interval of risk for these individuals is said to be censored. Thus, the numerator, that is, the number of individuals free of the event, and the denominator, namely, the number of individuals remaining at risk for the event, are both decreasing over time. For this situation, techniques analyzing survival or timed events are applicable to describe the data, such as the estimates based on the technique established by Kaplan and Meier to make survival curves.

Ordinal variables reflect a specific type of categorical level of measurement whereby the categories can be ordered, such that we know that one category is more or less than another category. The exact magnitude by which one category differs from another category, however, is not known, and remains only semi-quantitative. An example would be the subjective grading of valvar regurgitation or ventricular function from echocardiography. We would know that mild regurgitation across the mitral valve is less than moderate, but more than trivial. We do not know the exact magnitude by which the so-called trivial variant differs from that labeled mild, or how the mild variant differs from the moderate grade. The categories are discrete and ordered, and the values would be presented in a manner similar to other categorical variables, that is, as frequencies, proportions, and percentages. A common mistake with ordinal variables is to assign or code them with a numerical grade, and then to present or analyse them as if they were continuous variables, erroneously implying that an equal distance or magnitude exists between each numerical category.

Quantitative or continuous variables are those whereby the difference between two values reflects a quantifiable amount. In addition, a constant difference between two values across the spectrum of possible values always represents the same amount. For some continuous variables, there is a defined zero, a point at which the quantity reaches nil, and there cannot be a negative value. This is referred to as a ratio variable. Ratio variables are common, and examples include height, weight, age, ventricular ejection fraction, and blood pressure. We know the exact meaning of the absolute difference between two values regardless of those values. The difference between 120 and 100 cm in height is the same 20 cm as the difference between 80 and 60 cm in height. With a ratio variable, however, the difference from the defined zero allows the ratio to have meaning. For example, 120 cm is 1.2 times, or 20%, greater than 100 cm. For some variables, in contrast, there is no defined zero or point of absence. These are referred to as interval variables. The relative relationships between these values cannot be quantified. For example, it is possible to consider changes in ejection fraction in response to a medication. Some individuals will show worsened ejection fraction, and have a negative value, others will stay the same, while still others might improve, and exhibit a positive response.

The value recorded will reflect the quantity of the magnitude of change.

Since continuous variables can usually take on an infinite variety of values, reporting frequencies of values is meaningless, unless specific cut-points are used, or the values are grouped. Such categorisation of a continuous variable is rarely justifiable, nonetheless, since it overly simplifies the meaning and the presentation of the data, as well as diminishing statistical power. Continuous variables tend to take on a distribution, and the standard is to present some measure of the center of the values, along with the magnitude and pattern of their variation. The first step is to look at a frequency plot of the distribution of values. In general, some sort of bell-shaped curve will be observed, with a central hump tapering to the two sides. If the distribution is bell-shaped, we refer to this as being normally distributed. This implies that the centre, and the variance, has specific definable properties or parameters. The measure of the centre would be the mean or average value, calculated as the sum of all values divided by the number of values. For the mean of a perfect normal distribution, half of the values would be less, and half would be greater than this value. The measure of variation would be the standard deviation. This is calculated as the sum of the square of each of the differences between the values and the mean divided by the number of values. The standard deviation has specific properties in defining the proportion of values represented, and is an assumption supporting probability theory, which underlies statistical or inferential testing.

The normal curve, however, can be subject to distortion. If the central hump is abnormally peaked or flat, this is referred to as kurtosis. If the tails or the sides of the distribution are unequal, then there is skewness. Important kurtosis or skewness can cause the distribution to become abnormal. The standard parameters and characteristics of mean and standard deviation then no longer apply. In this case, measures of the centre might be chosen which reflect the ranking of values, and not their interval magnitude. In ranking all of the values, the median value would be that measured value at the 50th percentile. For skewed data, the greater the amount of skewness, the greater the difference between the median value and the calculated mean. Less frequently, the most common value, referred to as the mode, is taken as the measure of the centre. Measures of variation include values at specific percentiles, such as the quartile values, presented as the measured values at the 25th and 75th percentiles, with the interquartile range presented as the difference between these two values. Alternatively, the measured values at the 5th and 95th percentiles might be presented, or the minimum and maximum values. Since these values are not dependent on the distribution being normal, they are often referred to as non-parametric distributions. The use of non-parametric statistical testing tends to be less robust and less powerful than parametric statistical testing. Hence, mathematical transformations of the measured values may be performed to create a more normal distribution. This can sometimes be accomplished by calculating and plotting the logarithm or the square root of the measured values, or applying other types of mathematical transformations. The normalised transformed variable is then used in parametric statistical analyses.

Validity, Accuracy, and Reliability

In addition to level of measurement, variables have properties reflecting the impact of how the measurements were made or determined. These properties include validity, accuracy, and reliability. Validity is the property by which the measurement used is a true reflection of the desired concept. It answers the question, 'Am I really measuring what I think I am measuring?' Accuracy is the degree to which the measurement comes close to the truth in the subjects being measured. It is a property of the measurement tool itself, and often reflects systematic bias or error. Reliability is the degree of variation in the measurement that is attributable to application of the tool. This may reflect both systematic and random bias. For example, if the purpose of my measurement is analogous to shooting a gun at a target, validity is the degree to which I am aiming at the correct target, accuracy is the degree to which I come closest to the bull's-eye, and reliability reflects how closely multiple hits are clustered together. If the hits are tightly clustered together, but always to the right of the bull's-eye, then this may reflect a problem with the sight of the gun. The error is systematic, or reflective of a component of the system. If the hits are at, or close to, the bull's-eye, but widely scattered, then this may reflect some twitchiness or poor eyesight on the part of the shooter, or subtle variations in the bullets that influence their trajectory. The error may be both random and systematic. When using or interpreting a measurement, one must be aware of these properties of validity, accuracy and reliability. This becomes more important when attempting to measure more subjective concepts, such as quality of life or cardiac failure.

Validity can be an elusive entity to achieve when the concept or phenomenon being measured is more qualitative and subjective. Rather than a gold standard or criterion, it is usual to begin with a definition, and then attempt to develop measurable aspects that reflect that definition. If we take aortic regurgitation as an example, a subjective grading is often applied when performing echocardiographic assessment, characterised by ordinal categories of none, trivial or trace, mild, moderate, or severe, with some intermediate categories. The subjective or qualitative grade is meant to reflect the overall impression of the observer, and informally takes into account many aspects related to the concept being pursued, giving more weight to some than to others. If we wished to validate our subjective system of grading, we might start by convening a panel of expert echocardiographers and asking them first to define the concept of aortic regurgitation. There may be agreement that it has something to do with the volume of blood that re-enters the left ventricle via the aortic valve during diastole. Some may argue, however, that this would represent the total volume adjusted for the size of the patient. Others may argue that it would represent the proportion or percentage of the forward stroke volume ejected through the aortic valve. The panel of experts may agree that there is no method of echocardiography permitting quantification of this volume, but that indirect measures may exist against which the subjective grade might be compared. It is agreed that no single indirect measure will suffice, and that multiple aspects may need to be considered simultaneously. These indirect measures are chosen because they have validity of content, meaning that they are judged to

be related to specific aspects reflecting aortic regurgitation, and validity of construction, or construct validity, meaning that they are judged to have a plausible causal or physiological reason for having a relationship to aortic regurgitation. The panel may choose measures that reflect the state of the aortic valve in producing regurgitation, such as the width of the regurgitant jet relative to the width of the aortic outflow tract as measured using cross sectional and colour Doppler interrogation. They may choose measures that might reflect the volume of regurgitant blood, such as measurement of areas from colour Doppler mapping of flow, or even less direct measures, such as pressure half-time intervals or patterns of reversal of flow in the aorta as acquired using Doppler interrogation. They may choose measures that reflect the impact of aortic regurgitation on the ventricle, such as end-systolic and end-diastolic ventricular dimensions and volumes, as well as functional indexes such as shortening and ejection fraction. Alternatively, they may seek to measure this volume using other methods, such as with magnetic resonance imaging, or by creating an experimental model system. This process is aimed at criterion-related validity, or the degree to which the proposed measure relates to accepted existing measures. They may also seek to assess how the subjective grade relates to clinical or outcome measures, known as predictive validity. Subjective grading may be shown to relate to clinical symptoms, abnormalities of exercise capacity, ventricular dysfunction, or arrhythmias and sudden death, or to need for repair or replacement of the aortic valve.

If subjective grading of aortic regurgitation is judged, as based on content, construct, criterion-related and predictive validity, to be a valid measure of aortic regurgitation as it was conceived, then additional assessment is required regarding accuracy and reliability. Accuracy is a reflection of validity, but also includes any systematic error or bias in making the measurement. Systematic error refers to variations in the measurements that might always occur predominately in one direction. In other words, the deviation from the criterion or reference standard tends to be consistent. This may occur at the level of the tools or instruments used to make the assessment, and may represent lack of calibration. Regarding aortic regurgitation, this might reflect differences in the settings of gain or frequency of the probe used when the assessment was made. This may occur at the level of the observer, whereby the observer has a consistent bias in making the interpretation. Regarding aortic regurgitation, this might reflect the fact that some observers do not describe physiological amounts of regurgitation, and assign a subjective grade of none, and might not use intermediate grades. Alternatively, some observers may place more weight on a specific aspect when assigning a specific grade, such as areas as revealed by colour Doppler interrogation. This may also occur at the level of the subject, whereby a condition exists relative to the subject which biases the measurement. In terms of aortic regurgitation, this might reflect differing physiological conditions present in some subjects, such as concomitant mitral valvar regurgitation or aortic valvar stenosis.

Reliability or precision refers to the reproducibility of the measurement under a variety of circumstances, and relates more to random error or bias. It is the degree to which the same value is obtained when the measurement is made under the same conditions. Specific aspects of reliability

should be assessed. If we again consider aortic regurgitation, we would want to know that, if two observers assess the same subject using the same methodology, they would report the same subjective grade. This is referred to as inter-observer variability. We would also want to know that, if an observer repeats the assessment in same subject using the same methodology, he or she would report the same subjective grade. This is referred to as intra-observer variability. Both of these sources of variability would be determined using measures of agreement, and not correlations or associations. Some of the random variation in measurements may be attributed to the instruments, such as variations in settings, differing equipment, or different algorithms or processing. Some of the random variation may also relate to the subject, such as variations in physiological state, medications, or the position when the assessment was made.

Ideally, the assessment should be as accurate and reliable as possible. This would minimise variation in measurements related to systematic and random error or bias, and would improve statistical power, minimising the necessary number of subjects to be studied, or observations to be made. This can be optimised by standardizing as much of the assessment as possible. Training sessions for observers can be designed whereby criteria and skills for making the assessment and interpreting the results are reviewed and practised, so that they are applied in a uniform manner. Limiting the number of observers, and having independent adjudications, also improves reliability, particularly if the review is blinded. Having protocols in place that define and standardise all aspects of the assessment also improves reliability. This would specify the equipment, calibration, and settings to ensure quality control. It would also specify the conditions under which the assessment should take place, standardizing the setting and the preparation of the subject. Taking repeated assessments, and pooling the results within subjects, also reduces random error.

There are some additional features of measurement that may need to be considered. Sensitivity refers to the degree to which the value of the assessment can detect differences. If patients with clinically important differences in the volume of aortic regurgitation are both subjectively graded as moderate, then such subjective grading might not be sufficiently sensitive. An aspect of sensitivity is responsiveness, or the degree to which the measurement reflects change related to time or an intervention. If a medication results in a clinically important reduction in the volume of aortic regurgitation, but the subjective grade remains moderate, then this means of grading might not be a sufficiently responsive measure. Measurements should also be specific, being a measurement only of the entity of interest as it was defined. Measures of ventricular function, such as shortening and ejection fraction, may not be very specific indirect measures of aortic regurgitation, and may be more influenced by many other factors. The measurement should also have a sufficient distribution of responses. If the object is to study factors associated with aortic regurgitation after repair of subaortic stenosis, yet the population studied has mainly grades of none to mild, then such subjective grading may not be a good measure to use for the assessment of aortic regurgitation. When many measures that assess different or similar aspects of an entity are available, completeness and appropriateness should be balanced with efficiency or parsimony. In a study of aortic regurgitation,

all of the indirect measures could be assessed, as well as subjective echocardiographic grading, as well as some novel measures, which might include magnetic resonance imaging. This might provide the most complete assessment, but would be intensive in terms of time and resources, and might limit the recruitment of suitable subjects, as well as creating logistical issues regarding operationalisation, standardisation, and adjudication. It might also lead to inclusion of measurements that might be inappropriate to the aim of the study. It would be very complex to handle this large number of different measurements with different properties in an analysis aimed to address the question at hand. It would be preferable to focus on those measures which would give the highest level of measurement, in other words a continuous value, and which are valid, accurate, reliable, specific, sensitive or responsive, and parsimonious.

ANALYSIS OF DATA

Analysis is the method by which data or measurements are used to answer questions and generate knowledge, and then to assess the confidence in inferring those findings beyond the subjects that were studied. Analysis is often a secondary consideration when designing and implementing a study, and not considered until after the measurements have been made and the study is completed. In fact, the plan for analysis of the data is an integral part of the study protocol. It has an important relationship to the research questions being pursued, and a strong influence on the measurements to be made. Also, the chosen form of analysis can be an important tool to increase the validity of observed associations, by providing adjustment for potential sources of bias, such as confounding, or to determine more complex associations, such as interaction. The appropriate planning, strategy, execution and interpretation are essential elements to the critical appraisal of any research report.

What Is the Plan?

Research Question

Every study must begin with a well-defined question. The drafting of this question is the first step towards creating a research protocol. It is common to start with a topic of interest, or sometimes a clinical dilemma, and through consultation with experts, review of the published literature, and other sources of information, to define a discrete area of controversy to be addressed. Keeping track and documentation of this process often leads to the background section of a protocol, the reason for the study, and the introduction section of a subsequent manuscript. Often, constant revision, clarification, and specification of the question are required as part of this process. New investigators tend to be overly ambitious in their scope. The process of defining the research question often incorporates considerations of feasibility, relevance, novelty, and interest to the investigators. It is an iterative process that is not complete until a well-defined question, drafted in the form of a question, is finalised. It is not sufficient to only have objectives, aims, or purposes.

A well-defined question often suggests the design of the study, the population to be studied, the measurements to be made, and the plan for analysis of the data. It also

determines whether the study is descriptive or comparative. For example, in considering the topic of hypertrophic cardiomyopathy, a descriptive research question might be, 'What are the outcomes of hypertrophic cardiomyopathy?' In appraising this question, its overt vagueness would be noted. The first step would be to determine what answers are already known regarding this question, and what areas of controversy remain. The investigator might look at the question and the background review and ask some of the following: 'What outcomes do I wish to study?', 'How will I define hypertrophic cardiomyopathy and in what subjects?', 'At what time point or over what time do I wish to examine these outcomes?' In answering these questions, the research question is revised and further specified to 'What is the subsequent risk of sudden death for children with familial hypertrophic cardiomyopathy presenting to a specialised clinic?' This question suggests an observational study of a chosen cohort. Depending on feasibility for the investigators, the study may be conducted non-concurrently from existing medical record information, or concurrently by enrolling subjects in the present, and following them forward in time. The question also suggests the population of interest, and from this the investigators would develop criteria for inclusion and exclusion with definitions, and how the subjects would be identified from the specialised clinic. The measurements are also suggested, in that baseline characteristics would need to be obtained to define the criteria, and to describe the characteristics of the included subjects. The definitions and sources of data would need to be defined regarding detection of events of interest. The plan for analysis is suggested in that the question is descriptive, and would need to describe the proportion of subjects who would have experienced sudden death over a defined period of time, or more likely a time-event type of analysis would be performed. While the primary question here is descriptive, the investigators would be missing an important opportunity if they did not have secondary questions that explored the impact of treatments or risk factors on the risk of sudden death. It is rarely justified, or necessary, to perform a study that is only descriptive in nature. A well-defined and focused research question, nonetheless, is essential before considering other aspects of the proposed study or report.

Using Variables to Answer Questions

When the question is established, the next step is generating a plan for analysis so as to select and define variables. What information will be needed to answer the defined question? In the process of defining variables, should be given to considerations of their measurement. Specifically, definitions should be defined, sources of data determined, and issues of validity and reliability of measurements considered.

Classification

Variables can be classified for statistical purposes as either dependent or independent. Dependent variables are generally the outcomes of interest, and either change in response to an intervention or are influenced by or associated with factors. Independent variables are those which influence or are associated with the dependent variable. A detailed consideration of the question should clearly identify the key dependent and independent variables. Independent variables can be further classified. Some independent variables have a direct causal or predictive relationship with the

dependent variables, and are the variables in which we are most interested. Some independent variables have a direct influence on the dependent variables, but influence each other in the nature of that relationship. This is referred to as interaction. Some independent variables also have an indirect relationship with the dependent variables, primarily by their association with other independent variables that have a more direct association. This is referred to as confounding. Some dependent or outcome variables can become independent variables in their association with subsequent outcomes or dependent variables. An important step in creating a plan for analysis is to classify the available variables prior to considering how they will be described and related to one another in order to address the research question.

Outcomes or Dependent Variables

In any study, there are usually one or two primary outcomes of interest. There are often additional secondary outcomes, which are usually included to support the analysis based on the primary outcomes. If analysis of the primary outcomes is negative, conclusions from a study must be negative, regardless of those associated with the secondary outcomes. Analysis of secondary outcomes is also used for exploring or generating additional hypotheses and should not represent a definitive analysis. It should be recognised that the greater the number of outcomes examined in a study, the more likely it is that statistical significance will be reached on at least one of them. This is the challenge of multiple comparisons. With advances in management of many diseases and conditions, some outcomes have become increasingly rare, and many studies are grouping outcomes into composite outcomes. An example might be creating a composite outcome of death, myocardial infarction, or stroke in a clinical trial of cardiovascular risk factor reduction. The appropriateness of composite outcomes is questionable, and issues have been raised about their validity.¹ First, not all possible outcomes that might be included in a composite outcome have the same importance for subjects. Second, the creation of a composite outcome might obscure differences between the individual outcomes. The risk for the component outcomes may be different, as well as the impact of therapy or associated variables. Specific outcomes should be favored over composite outcomes when feasible and relevant.

Outcome variables can differ in their nature, which influences how they should be handled in an analysis plan. Some outcomes are discrete, being either present or absent, or classified into nominal categories. Some outcomes can be ordinal or continuous in nature, indicating a degree or magnitude. Some outcomes are discrete events that have a relationship with time. These outcome events may be repeated or recurrent, and subjects may be simultaneously at risk for different and mutually exclusive outcome events that may compete. Some outcomes may evolve over time, and thus have a longitudinal dimension or trend over time. Each of these features needs to be considered, as specific methods of data and statistical analysis need to be applied.

Independent Variables

Independent variables are variables for which an association with the dependent variables is sought. These variables can include subject characteristics and interventions, but sometimes outcomes that may be predictive or causal of

other subsequent outcomes. The research question should define the primary independent variable, which is commonly a specific treatment or a key subject characteristic. Independent variables can be grouped according to the proposed nature of their relationship with the dependent variable, which is described in more detail in a subsequent section. We usually have some independent variables in which we are interested whether or not they have a direct predictive or causal relationship with the dependent variable. We also have some independent variables in which we are less interested, but which may act as potential confounders.

Planning the Description

The first step in the plan for analysis is to define how all of the variables are to be described. The methods by which this is done have been covered in a previous section. In describing data, the results or values of each individual variable are summarised. Description is important in detailing the characteristics of the subjects to be studied, usually at baseline, and will allow the reader of a subsequent report to determine if the results of the study might be applicable to their own clinical practice. Description of the data also can give the details of what interventions were performed, and what outcomes occurred. Additionally, we can describe data that were collected in order to establish compliance with the study protocol. This might include compliance with therapy, co-interventions, cross-over from assigned treatment, duration of follow-up and completeness of follow-up. Description is also used to determine issues that might have an impact on statistical testing, such as extreme values or outliers, missing values, categories with too few values, and skewed distributions.

Planning to Establish Relationships and Associations

This step in the plan is guided by the research question. The aim of most research questions will fall into one of three main categories. Some studies aim to answer questions about the effect of a treatment, either alone or in comparison with either no treatment or an alternative treatment. In this case, the treatment is the primary independent or predictor variable, and there can be many different outcome or dependent variables. If the study is comparative, then the characteristics of the subjects should be compared at baseline for the groups. We also need to compare additional management that might have occurred. If the treatment allocation was randomised, then comparison of baseline characteristics determines the success of equivalency between groups. If the treatment allocation was not randomised, the comparison of baseline characteristics might highlight important or relevant differences between groups that could potentially confound comparisons of outcomes, and for which statistical methods for adjustment should be used.

The second category includes those research questions aimed at determining the prognosis of subjects with a common characteristic or after a specific intervention, the risk of a particular adverse outcome, or factors that might be predictive or associated with prognosis or risk, particularly those of a potential causal nature. The dependent variable is the outcome variable of interest, and associations are explored with multiple independent variables that may include subject characteristics, interventions and other outcomes. This type of analysis plan should take into account independent variables that may serve as potential confounders, and that have a direct relationship to the outcome, but are also associated with the independent

variable of interest for which we would like to infer a direct relationship with the outcome.

The third category includes those questions aimed at identifying factors that may discriminate or differentiate different groups of subjects. Some of these questions may be aimed at evaluating a diagnostic test. In this case the dependent variable is the group status of the subjects, usually as defined by application of a criterion standard, and the primary independent variable is the result of the diagnostic test. Some questions may be aimed at contrasting characteristics between two or more defined groups of subjects. Case-control studies are a classic example. In this case the primary dependent variable is the characteristic by which the cases and controls were defined, and multiple independent variables including subject characteristics, interventions and outcomes are contrasted.

Types of Relationships Between Variables

An important defining feature of variables, in addition to the level of measurement and measurement properties, is the relationship between them. Variables can be classified in terms of their relationship to one another. Independent variables are those variables which incite, influence or are associated with a response. The response variable is termed the dependent or outcome variable. Independent variables may have a direct association with the dependent variable, either through prediction or causality, or they may have an indirect or confounding association.

Causality is a desired feature of associations we wish to determine. The aim of many studies is to determine relationships that are cause leading to effect. The nature of associations and features of study designs that help to give confidence that a discovered association is cause and effect will be described later in this chapter, but include evidence of a correct temporal relationship, a strong dose-response relationship, freedom from bias, consistency, and biological or pathophysiological plausibility. When we cannot be certain that the temporal relationship is correct, that the potential causal factor was present first and led to the subsequent development of the effect or outcome, we cannot exclude that the relationship between the two variables is actually reversed. In this case the putative causal factor may actually be caused by the assumed effect or outcome. For example, in a cross sectional study of treatment with β -blockers, we note that the use of β -blockers and the presence of palpitations are significantly associated. We might erroneously conclude that β -blockers are causal of palpitations, when in fact arrhythmia causing palpitations has led to treatment with β -blockers.

Confounding occurs when the independent variable exerts its influence or association with the dependent variable primarily through its relationship with a further independent variable that is more directly related to the dependent variable. The identification and adjustment for confounding can be a challenge in the analysis and interpretation of observational or non-experimental study data. Confounding is most likely to occur when independent variables are highly related or correlated with one another, which is referred to as colinearity. For example, a hypothetical study shows an association between increased use of systemic anticoagulation and increased risk of death after the Fontan procedure. Consideration is given to

recommending against the use of routine anticoagulation. Further analysis, however, may reveal that the use of systemic anticoagulation was predominately in those patients with poor ventricular function. Poor ventricular function is then found to be causally and strongly related to mortality, and the association of anticoagulation with mortality is felt to be confounded and hence indirect because of its increased prevalence of use in patients with poor ventricular function. Stratified or multi-variate analyses are often used to explore, detect, and adjust for confounding, and to determine relationships between variables that are independent of other variables.

Interaction is a particular type of relationship between two or more independent variables and a dependent variable. The relationship between one independent variable and a dependent variable is influenced or modified by an additional independent variable. For example, in our hypothetical study, further analysis shows that the relationship between systemic anticoagulation and mortality is more complex. For patients with poor ventricular function who are treated with systemic anticoagulation, mortality is less than for those not treated. For patients without poor ventricular function, there is no difference in mortality between those treated versus those not treated with systemic anticoagulation. Thus, there is a significant interaction present between systemic anticoagulation and poor ventricular function, demonstrated by the differential association of anticoagulation with mortality as influenced by the presence of poor ventricular function. In order to be certain that the anticoagulation was the true cause of the reduction in mortality, and not attributable to some other unmeasured confounding factor, a properly designed and executed randomised clinical trial should be undertaken.

Statistical Analysis—Detecting Associations and Relationships with Confidence

Opinions about the extent of statistical knowledge of physicians vary widely. On the one hand, conducting or appraising clinical research sometimes requires knowledge of increasingly complicated statistical methodology. On the other hand, little time in medical school is available appropriately to address statistics and their use and applicability in clinical practice. A recent survey of 171 articles published in the journal *Pediatrics* found that nine-tenths of published studies used some sort of inferential statistics. The same study found that a reader who understands descriptive statistics, proportions, risk analysis, logistic regression, *t* tests, non-parametric statistics, analysis of variance, multiple linear regression and correlations could still only fully understand the analysis in just under half of the articles.² Despite disagreements on the extent of statistical education in clinical training, the increasing complexity of statistics reported in the medical literature clearly appeals for a standard of at least some statistical literacy among practicing clinicians and clinical researchers.

Principles of Probability and Probabilistic Distribution—The Science of Statistics

While conducting a census of every citizen of a given country, you find that the proportion of women in the population is exactly 52%, and that their average height is 152 cm.

You select a random sample of 100 people from this same population and, to your surprise, 55% of your sample is composed of women and their average height is 149 centimeters. Subsequently, you decide to select a second random sample of 100 people. This time, 47% of your sample is women and the average height is 158 centimeters. The phenomenon at play here is called random effect, random error, or random variation. Each individual sample taken randomly from a larger population will have an uncertain distribution in terms of characteristics. The distribution of characteristics in each sample, nonetheless, is based on the probability of those outcomes for the entire population, which has a specific distribution of features known as parameters.

If you flip a coin, the probability of the coin landing on heads is exactly 50%. If you flip that coin 100 times you might get 50 heads, as you would expect, but owing to random effect you may get 49 or 52 heads, and on rare occasions 45 or 55. If you repeat this exercise numerous times, you will get exactly 50 heads a few times, most of the times you will get somewhere between 48 and 52 heads, and in the great majority of tries you will get between 45 and 55 heads. The outcome of each series of 100 tosses is random, but remains a function of the true probability of getting a head with each coin toss. If we were to plot the frequency of heads in our many samples, we might see a bell-shaped curve centered at or very close to 50 that slopes to the right and the left, with more extreme values occurring less frequently in the tails. This curve is called a distribution of probability. It has some specific properties about the variation that allow us to be able to predict how frequently a given outcome will be observed in an infinite number of random samples.

Inference Based on Samples from Random Distributions

When we measure something in a research study, we may find that the values from our study subjects are different from what we might note in a normal or an alternative population. We want to know if our findings represent a deviation from normal, or whether they were just due to chance or random effect. Inferential statistics uses probability distributions to tell us what the likelihood might be for our observation in our subjects, given that our subjects come from a larger population which forms the basis for the probability distribution. We can never know for certain if our subjects truly deviate from the norm, but we can infer the probability of our observation from the probability distribution. If that probability is low, we can feel confident in our conclusion. In general, we assume that if we can be 95% certain, and accept a 5% chance that our observation is really not different from normal, or the center of the probability distribution, then we state that our results are significant. The probability that the observed result may be due to chance alone represents the *P*-value of inferential statistics.

When a random sample is selected from a population, differences between the sample and population are due to the random effect, or random error. In our census, while the entire population had an average height of 152 cm, it does not mean that everyone in this population was 152 cm tall. Some were 130 cm in height, and others were 170 cm. Hence, if you select a random sample of 100 people, some will be taller and some shorter. By chance alone, it might be that a specific sample will have fewer shorter

people or fewer taller people. Thus, the average height for this specific sample might be lower or higher than the average by chance alone. The key point to remember is that as long as the sample was randomly chosen, the mean of your sample should be close to the mean of the population. The larger your sample, the more precise the measurement is, and the closer you are to the true mean of 152 cm. This is because each value contributes less to the total and, as such, extreme values have less of an effect. The same is true with the example of coin tossing. Out of 10 tosses, a result of heads for 90% or 10% of tosses is rare but not impossible. If the coin toss is repeated 1000 times, the results will certainly be much closer to the 50% probability of a single coin toss. The fact that the result is different from that in the population from which the sample was taken does not necessarily imply that the subjects in your samples are inherently different from that population. This might just be due to random error.

Consider a situation in which a researcher polls a random sample of 100 paediatric cardiologists regarding their preferred therapy for failure, and found that 72% of the sample prefers using drug A over drug B. Since the sample was chosen at random, the researcher decides that it is a reasonable assumption that this group is representative of all paediatric cardiologists. A report is published entitled 'Drug A is preferred over drug B for the treatment of heart failure in children'. Had all paediatric cardiologists been polled, would 72% of them have chosen drug A over drug B? If another researcher had selected a second random sample of 100 paediatric cardiologists, would 72% of them also have chosen drug A over drug B? The answer in both cases is probably not, but if both the samples come from the same population, and were chosen randomly, the results should be close. Consider that a new study is subsequently published that reports that drug B is actually better than drug A. You then poll a new sample of 100 paediatric cardiologists and find that only 44% still prefer drug A. Is the difference between your original sample and your new sample due to random error, or did the publication of the new study have an effect on preference in regard to therapy for children in heart failure? The key to answering this question is to estimate the probability by chance alone of obtaining a sample in which 44% of respondents choose drug A when, in fact, 72% of the population from which the sample is drawn actually prefers drug A. In such a situation, inferential statistics can be used to assess the difference between the distribution in the sample as opposed to the population, and the likelihood or probability that the difference is due to chance or random error.

Relationship between Probability and Inference

A detailed explanation of the exact methods used to determine if the probability distribution of the sample is different from or similar to that of the overall or target is beyond the scope of this chapter. Suffice to say that each type of data, and each specific question, requires specific methodologies and tests, some of which will be briefly introduced later. The common point of any statistical test is that all types produce a *P*-value, which represents the probability that two distributions are similar. Statistical testing takes into account the number of subjects being tested, the observed variation in the data, the magnitude of any differences, and the underlying nature of the probability distribution, and thus the results are influenced by

these features. Every statistical test comparing two groups starts with the hypothesis that both groups are equivalent. A two-tailed test tests the probability that group A is different from group B, either higher or lower, while a one-tailed test tests the probability that group A is either specifically higher or lower than group B, but not both. As a general rule, only two-tailed tests should be used in most situations, as they assess the probability of two groups being different without any presumptions about the direction of the difference between groups. There is no assumption that A is higher or lower than B, just that the two are different. One-tailed tests assume that the difference observed has a direction, for example, higher or lower, but not both. These tests should be used only in specific situations, an example being a non-inferiority trial. By convention, statistical significance is reached when the *P*-value obtained from the tests is under 0.05, meaning that the probability that both groups are equivalent, and not different, is lower than 5%. The *P*-value is an expression of the confidence we might have that the findings are true and not the result of random error. From our previous example of preferred treatment for heart failure, the *P*-value was less than 0.001 for 44% being different from 72%. This means that in a population where 72% of cardiologists prefer drug B the probability of having a random sample with 44% favoring drug B is less than 1 in 1000 trials. We can confidently conclude, therefore, that the second sample is truly different from the original sample, and that the opinion in the population of paediatric cardiologists had changed.

Relevance of *P*-values

Limitations

The threshold of $P < 0.05$ for defining statistical significance is acknowledged to have been selected somewhat arbitrarily, and is consequently a subject of debate. With this in consideration, it is important to bear in mind the implications and meaning of a *P*-value. Statistical testing takes into account the number of subjects being tested, the observed variation in the data, the magnitude of any differences, and the underlying nature of the probability distribution, and thus the results are influenced by these features. The magnitude of any difference is only one component, yet many assume that if the *P*-value is less than 0.05 then the results are important and meaningful. This is not the case, since a *P*-value only is a measure of confidence. *P*-values are highly dependent on the number of study subjects or observations. As the size of the sample increases, the precision of the estimate around the true mean increases, and thus the random error decreases. With large enough samples, the random error will be close to zero, hence very small differences or associations could meet the confidence threshold, yet be unimportant. With a sample size of 10,000, a *P*-value of 0.04 is probably of limited interest because the large size of the sample will ensure that even very small differences will be statistically significant. On the other hand, with very small samples, statistical significance at $P < 0.05$ is much less likely to occur even with large differences or associations. With small sample sizes, a non-significant *P*-value implies that we do not have sufficient confidence in the result, not that it might represent an important difference or association. *P*-values are only a measure of confidence, and the results must always be considered in light

of the magnitude of the observed difference or association, the variation in the data, the number of subjects or observations, and the clinical importance of the observed results.

Clinical Relevance versus Statistical Significance

A primary consideration regarding statistical analysis in medical research is the difference between statistical significance and clinical relevance. There is no real value to an association that is highly statistically significant but clinically or biologically implausible. Likewise, studies with results that are clinically important but not statistically significant are of uncertain value. This is a key concept that is not widely acknowledged. Statistical significance does not necessarily equate to clinical relevance and, similarly, a result that is not statistically significant might be clinically important. Statistics are a tool to describe and to uncover evidence regarding the underlying mechanism of disease and impact of therapy, but it is important to know how to translate statistical knowledge into clinical knowledge.

Assessing the clinical relevance of an observed difference or association and the impact of random effect can be helped by examining the confidence interval. Confidence intervals are important tools to assess clinical relevance as they are intrinsically linked to a statistical *P*-value, but give much more information. The confidence interval is a representation of the underlying probability distribution of the observed result, based on the sample size and variation in the data. A 95% confidence interval would encompass 95% of the results from similar samples with the same sample size and variation properties, and thus represents a wider range of values over which we can be confident that the true result might lie. We can also construct a 70% confidence interval if we are willing to accept a greater chance of random error.

The confidence interval gives us the greatest information regarding the possibility that we have made an error in the interpretation of the results. The confidence interval asks two questions: first, what is the likely difference between groups, and second, what are the possible values this difference might have? For example, the randomised clinical trial testing the effect of drug B for children in cardiac failure found a reduction in mortality with drug B compared to drug A, but the *P*-value was greater than 0.05 and hence the result did not achieve statistical significance, or a sufficiently high level of confidence. Before we conclude that there was no relative benefit to drug B, we need to examine the result and the confidence interval. The trial randomised 60 patients equally to the two drugs. The mortality after 5 years was 40% with drug A and 20% with drug B, giving a 20% absolute difference in mortality after 5 years with drug B relative to drug A (−20%). We calculate a number needed to treat of 5 patients, meaning that based on this result we would need to treat only 5 patients with drug B in order to prevent one death relative to treatment with drug A. The 95% confidence interval, however, ranges from −41% to +3% and the *P*-value is 0.09. Based on the *P*-value, we might mistakenly conclude that there is no benefit to drug B. The 95% confidence interval from this sample suggests that, if the true size of the effect is −20%, 95% of random samples would have a difference in mortality ranging from a 41% reduction in mortality with drug B compared to drug A through to a 3% increased mortality with drug B compared to drug A. We are 95% confident that the truth lies somewhere between these two points, and since the

interval includes the value 0%, we cannot confidently conclude that there is a difference between the two drugs. We also cannot confidently conclude that there was not an important difference between the two drugs, including a benefit as great as a 44% absolute reduction in mortality with drug B. It then becomes difficult to know what to conclude from this study. This situation most commonly arises when we have an insufficient number of study subjects or observations. We can calculate the power of this study, which is the probability of concluding that there was benefit with drug B when in truth there really was a difference. Based on the observed findings and the number of subjects studied, the power would be 0.29, meaning that if we conclude that there was a benefit of a 20% absolute reduction in mortality with drug B over drug A, we would have only a 29% chance of being correct. We might suppose that a 4% difference in mortality would be the smallest effect that we would consider to be clinically relevant and would prompt us to prefer drug B over drug A, with a number needed to treat of 25. With our observed difference of 20% and our sample size, we would have a power of 0.89 to detect this effect of 4%, meaning that we could conclude that the benefit of drug B is at least a 4% absolute reduction in mortality relative to drug A with an 89% chance of being correct.

Type I and Type II Error and Power

A study can have one of four possible conclusions. Two are desirable. We might truthfully conclude from our results that a difference or association exists or does not exist, with confidence. Alternatively, we can incorrectly conclude that a difference or association exists or does not exist, when in truth the opposite is true. Although the *P*-value is a highly useful statistical indicator, it is an imperfect one and we cannot rely on it as the sole piece of information on which to base a conclusion. Results drawn from samples and inferred to a target population are susceptible to two types of error: type I error and type II error. A type I error is one in which we conclude that a difference or association of a certain magnitude exists, when in truth it either does not or is less. From probability distributions, we can estimate the probability of making this type of error, which is referred to as alpha. We also know this entity as the *P*-value, or the probability that we have made a type I error. Such errors are evident when a *P*-value is statistically significant, but there is no true difference or association. With a *P*-value of 0.05, we are taking a 5% likelihood that our conclusion is incorrect, and the results are due to chance or random error. In a given study, we may conduct many tests of comparison and association, and each time we are willing to accept a 5% chance of a type I error. The more tests that we do, the more likely we are to make a type I error, since by definition, 5% of our tests may reach the threshold of a *P*-value less than 0.05 by chance or random error alone. This is the challenge of doing multiple tests or comparisons. In order to avoid making this error, we can lower our threshold for defining statistical significance, or we can perform adjustments that take into account the number of tests or comparisons being made. Alternatively, we can report only those comparisons or associations that are significant in multi-variable analyses.

The second error which is of concern is the so-called type II error. In this situation, we might conclude from the results in our sample that there is no difference or association, when in truth one exists. We can determine the probability

of making this type of error, called beta, from the probability distribution. Beta is most strongly influenced by the number of subjects or observations in the study, with greater number of subjects giving a lower beta. We can use beta to calculate power, which is $1 - \text{beta}$. Power is the probability of concluding from the results in our sample that a difference or association exists when in truth it does. It is a useful calculation to make when the P -value of a result is non-significant, and we are not confident that the observed result is due to chance or random error. Before we conclude that there is no difference or association, we need to be sure that there was sufficient power in order to detect reliably an important difference or association. If we can be fairly certain that we can exclude the fact that we might be missing a clinically important difference or association, we can be confident in our conclusion. We calculate the power in order to determine what might be the likelihood that a difference or association truly exists based on our observed results and the number of subjects we studied. As a general rule, a study reporting a negative result needs to have a power of at least 80%. This means that we are 80% sure that the negative results from this study are not due to a failure to reject a difference, when there is actually one. We are taking a 20% chance of making a type II error.

Applying Statistical Testing

Techniques for analysis of data are used to describe characteristics and to determine associations. Statistical analysis is then used to determine the likelihood that the observed differences or associations are due to chance or random error, and gives us confidence in inferring the results from our study sample to the target population. The selection of statistical test depends on the level of measurement of the dependent and independent variables. It must be remembered that statistical analysis is strictly a mathematical operation based on both facts and assumptions, and that meaning comes from our interpretation of the variables and the results. As such, we must ensure that we are first specifying a hypothesis, performing the appropriate statistical tool, and then interpreting the result. We must avoid the situation where we have a certain result in mind, and then apply different manipulations of the variables and statistical testing to achieve an analysis that supports that result.

Comparing Two or More Groups or Categories

The most common type of plan for analysis involves the comparison of two or more groups defined by a particular characteristic or treatment. The group assignment represents the independent variable, and we seek to determine differences in characteristics and outcomes which are the dependent variables. The simplest form of comparison between two groups is the comparison of two dichotomous or binomial variables from a two-by-two cross-tabulation table using a chi-square test, which compares the variables based on the probability of obtaining a given distribution of dichotomous outcomes. The chi-square test becomes inaccurate when any cell in the cross-tabulation table has less than 5 subjects or observations, and a Fisher exact test is then used. The chi-square test can be applied if there are more than two categories for either the dependent or independent variable or both. Again, if any cell in the cross-tabulation table has less than 5 subjects or observations,

the chi-square test cannot be reliably applied. Categories should then be combined in a logical manner until all cells in the table have 5 or more subjects or observations, then the chi-square test can be applied. If the categories of the dependent variable are ordinal in nature, then a Mantel Haentszel chi-square test can be an indicator of trend. Chi-square testing contrasts the difference between a distribution of values in the cells of a cross-tabulation table that would be expected if they were distributed at random, versus the observed distribution. The difference between the observed and expected result is then related to the chi-square probability distribution to determine whether the difference is sufficiently unlikely.

When the dependent variable is continuous, and the independent categorical variable has only two categories or groups, then the Student t test is applied. The probability of the observed difference relative to an hypothesis that there is no difference is derived from the t probability distribution. When there are more than two groups or levels, then an analysis of variance is applied, with use of the F distribution. If the dependent variable is a highly skewed continuous variable or an ordinal variable with many levels, then a nonparametric analysis of variance may be needed that utilises ranks rather than the actual values.

Correlations and Associations

In specific circumstances a statistical test is aimed not at comparing two groups, but at characterizing the extent to which two variables are associated with each other. Correlations estimate the extent to which change in one variable is associated with change in a second variable. Correlations are unable to assess any cause-and-effect relationship, only associations. The strength in the association is represented by the correlation coefficient r , which can range from -1 to 1 . An r value of -1 represents a perfect inverse correlation, where an increase of 1 unit in a variable is exactly associated with a decrease of 1 unit in the other. Conversely, an r value of 1 is a perfect correlation, where an increase of 1 unit in a variable is exactly associated with an increase of 1 unit in the other. An r value of zero indicates that a change in one variable is not associated with a change in the other, meaning that both variables are independent of each other. Correlation coefficients are directly proportional to the strength of the association between the variables. P -values for correlation coefficients represent the probability that there is no association between the variables, or an r value of zero. There are many types of measures of association for assessing the relationship between two categorical variables. For two ordinal variables, Spearman rank correlation is used. For two continuous variables, Pearson correlation is used. Underlying the analysis of association between two continuous variables is a regression line, with the correlation coefficient representing the amount of variation around that line.

Matched Pairs and Measures of Agreement

Usually measurements for a study are independent of one another. For example, we may wish to compare measurements made in two groups of subjects where we know that the groups are composed of separate individuals that bear no relationship to one another. In order to reduce variation or to control for a given factor, we may create pairs of individuals matched for a common characteristic. Alternatively, the two groups may not be independent but have an individual level relationship, such as a group of subjects

and a group of their siblings. The subjects and their sibling represent matched pairs. When this is the case, we must use statistical testing that takes into account the fact that the two groups are not independent. If the independent variable is categorical, we would use a McNemar chi-square test. If the independent variable is ordinal, we would use an appropriate nonparametric type of test, such as Wilcoxon signed rank test. If the independent variable is continuous, we would use a paired t test. Each of these tests would relate to a different and specific type of probability distribution.

Sometimes, we will make repeat measurements in the same subject but using different methodology. By their nature, it is not surprising that the measurements will correlate, since they are measuring the same thing. What we are actually interested in is the degree to which the measurements agree, or agree with a criterion standard. Agreement between two binary variables can be expressed in one of two ways, either through the raw agreement or through the chance corrected agreement. The raw agreement is merely the number of times two measures agree divided by the total number of measures. By chance, two binary variables will agree approximately half of the time. Based on this, raw agreement is of limited interest. Cohen's kappa or chance-corrected agreement is the degree of agreement between variables beyond that expected by chance alone. When continuous variables are of interest, agreement is assessed and depicted using Bland-Altman plots. A Bland-Altman plot plots the difference between two measurements in a pair on the y-axis versus the mean of those two measurements on the x-axis. If the agreement were perfect, all of the points would be at a difference of zero regardless of the value of the measurement. The plot can show the degree and limits of agreement, but also any patterns. Systematic bias can be noted, as well as changes in the magnitude of agreement as the average values get larger or smaller. A paired t test can be used to determine if any systematic differences exist between pairs of measures.

Linear and Logistic Regression Models

Often the relationship between two variables can be represented by a line. For continuous dependent variables, that line can be straight, in which case the analysis would be a simple linear regression. Sometimes the relationship is more complex over the range of values of the dependent variable, and may not be linear. In this case, transformations of dependent and independent variables may be used, or non-linear regression techniques can be applied. If the dependent variable is dichotomous, then the relationship is between the probability of a value of the dependent variable as a function of the independent variable. In this case, a logistic regression or log-linear technique would be used. These different regression techniques can be applied to incorporate the relationship between the dependent variable and multiple independent variables. The relationship between the dependent variable and each independent variable would then be independent of the effect of the other independent variables included in the analysis. The output is in the form of an additive mathematical equation, called a regression equation, whereby the value of each independent variable is weighted in its effect on a baseline value called the intercept. The weighting factors are called regression coefficients or parameter estimates, and take into account the level of measurement of the variable and its units of measurement. Regression

equations are useful in determining the independent effect of specific variables of interest on a given dependent variable, by allowing the investigator to account for bias resulting from potential confounding factors. Statistical testing can be applied to the whole regression equation, and to the individual variables that were included. Interaction can also be explored within regression modeling by incorporating interaction terms as additional independent variables in the equation.

Survival or Timed-event Analysis

Since death is a certain event for all of us, if you follow every subject in a cohort for an infinite amount of time, your cumulative survival will eventually reach 0%. If a study reports that the survival of a cohort of subjects is 50%, the number is meaningless unless the time interval over which that survival was accrued is also reported. Additionally, we would need to be assured that all of the surviving subjects at risk are accounted for. One of the challenges of following cohorts is that subjects may be lost to follow-up or be lost to further observation before they achieve the event of interest, which is known as censoring. For estimates of survival, subjects may be dropping out of the numerator as they achieve the event of interest, but also out of the denominator as they terminate their contribution to the cohort. In order to accurately depict this phenomenon over time, we need to continuously account for these changes to the cohort. We also need to line up the subjects at a common starting point. In order to correctly assess time-related events, a time-related analysis should be used. Common events that are studied include death, intervention and repeat intervention. The events must occur at a discrete time point. Common starting points that are studied include birth, presentation, diagnosis and intervention. They must also be at a defined discrete time point. For an analysis of survival from birth, every subject is assigned an interval to either death, or to the end of the observation period at which they were last known to be alive. The proportion of subjects surviving to a given time point is continuously calculated, with subjects who die dropping out of the numerator and denominator, and subjects ending their period of observation but still alive dropping out of the denominator, representing the remaining patients alive and at risk of death at a given time point.

The most common form of survival analysis is to calculate and plot non-parametric Kaplan-Meier estimates. We can use statistical tests to determine whether independent variables have an association with time-related survival using Wilcoxon and log rank tests. We can use a particular type of regression analysis which handles time-related events as the dependent variable by using Cox's proportional hazard regression modeling. This allows us to explore the independent relationship with multiple independent variables, with the parameter estimates representing risk ratios.

If we wish to use independent variables to predict time-related survival, we can use mathematical modeling of the underlying rate or hazard at which events occur. Parametric analysis techniques are increasingly being used, and survival models can be derived which encompass three phases of time-related risk: early, constant, and late. Independent variables associated with each phase can be modeled separately. From this type of analysis, we might discover that the factors associated with early mortality are not the same as those associated with late mortality. One of the most

interesting applications of parametric survival models is the creation of competing risk models. Competing risk analysis establishes the likelihood of subjects to have achieved one of two or more mutually exclusive events over time for which they are simultaneously at risk. The competing risk analysis estimates, at each time point, the likelihood of each competing event occurring against all others, based on a parametric survival model for each event. An excellent example of how this might be applied was a study of outcomes after listing for heart transplantation.¹ After listing, a patient may die without getting a transplantation, may have a transplantation, may be taken off the list if they no longer require a transplantation because they improve or because they develop complications that preclude transplantation, may have an alternative procedure, or may remain on the list surviving without having any of the previously mentioned events. A given patient is simultaneously at risk for all of these mutually exclusive events or end-states. The rate at which patients are achieving these events over time can be modeled mathematically and associated factors determined. These rates and their associated factors can then be used for prediction. We can determine the likelihood of a patient with a given set of characteristics receiving a transplantation at a given point in time, remaining on the list, being removed from the list, or dying. The advantage of competing risk analysis over multiple survival curves is that every subject is calculated once and not censored in multiple different curves.

Longitudinal or Serial Measures Analysis

The value of some variables can change over time if we measure them repeatedly, and trends can be noted. Examples might be changes in left ventricular ejection fraction or subjective grade of mitral valve regurgitation. If we measure something repeatedly in a subject, then the measures are not independent, and we need to account for this in the analysis. If the measurements occur at discrete and common time points across subjects and there is little missing data, then a repeated measures analysis of variance can be used. This is rarely the case using clinical data, since patients rarely all have measurements at the same time, some patients may have more measurements than others and may have been followed longer, and there may be variable amounts of missing data. We may also wish to determine if independent variables are associated with the measurements and with changes over time. Specific types of regression analyses have been developed and applied to handle this type of complex data. If the serial measurements are of a continuous variable, then mixed linear or non-linear regression analysis can be used. The effect of time course can be included as an independent variable, and interactions with time and other independent variables can be explored to determine associations with trends. If the variable is categorical or ordinal, then a general estimating equation type of regression analysis can be used.

Accounting for Non-random Allocation in Comparison of Therapies

Non-random allocation of patients to therapies is one of the limitations of using observational clinical data to compare therapies. Patient characteristics that influence the selection of particular therapies may also influence the outcomes of those therapies, and hence bias any comparison. This is especially true for patients receiving new and higher risk therapies, since they are often the patients with

the most severe/active disease and are the ones expected to have the worst clinical outcomes. The statistical analysis should include the methodology to adjust for non-random assignment to therapy, and to equalise comparisons. One method often used is the creation of a propensity score.³ A propensity score is the probability, based on a subject's characteristics, that the subject would have been selected for a specific therapy versus the alternative. The propensity score is derived from a logistic regression model with the treatment assignment as the dependent variable, and all known subject characteristics as independent variables. The logistic regression equation is then solved for each subject and converted to a probability, which is the propensity of that subject to have been selected to the specific therapy. The propensity score can be used in three different ways. The first method uses the propensity score to select and create pairs of subjects, one from each treatment group, that are matched according to the score. The second method recreates a blocked randomised controlled trial by dividing subjects within treatment groups into tiers, quartiles or quintiles based on their propensity score. Outcomes for each block in the treatment group are then compared against those for the corresponding block in the alternative group. These two uses of the propensity score often require a large number of patients and imply that the propensity score will be balanced and sufficiently overlapping between treatment groups, which is not always the case. When propensity scores are highly unbalanced between groups and little or no overlap exists, the score can be used as an adjustment factor or an additional independent variable in regression analysis. Using the propensity score as an independent variable in regression equations is how it is most commonly used. The use of propensity scores, and other forms of statistical adjustment for potential confounding, only adjusts for those variables that are measured. It does not replace randomisation, which randomly distributes not only measured but unmeasured factors as well, and gives the greatest likelihood of an unbiased comparison.

Seeking Statistical Expertise

One of the key elements of data and statistical analysis is to know when to seek the assistance of a statistician. There are several statistical software programmes available for performing analysis, and some are more user friendly than others. Nearly all will allow you to perform statistical analysis without knowledge of the underlying mathematics and assumptions on which the tests are based, which increases the chances for a novice to make important errors regarding inappropriate application. In general, most individuals can handle the description of data, and do some simple testing where two variables are involved. Analysis which incorporates multiple independent or dependent variables, such as most forms of regression analysis, in contrast, should be performed with the guidance of or by a statistician. Additionally, consultation should also be obtained for instances where types of nonparametric tests are needed. We might sometimes think that statisticians speak a different language, but it is important to remember that for the majority of statisticians your data is but numbers, without meaning. It is essential, therefore, when enlisting a statistician, that your data be clearly organised and defined and that you have a detailed plan of how the analysis should proceed. This should be

discussed with the statistician, and any questions answered and misinterpretations clarified. The role of the statistician is to apply the most appropriate technique given the level of measurement and assumptions about the data, to report the results, and to assist in the interpretation.

CRITICAL APPRAISAL OF THE LITERATURE

It is increasingly important for clinicians to have sufficient skills in order critically to appraise the quality and relevance of studies being published, especially in an era which has seen an exponential growth in the number of scholarly journals and reports. These reports, whether they are guidelines or clinical trials, constitute the evidence that is incorporated into the practice of evidence-based clinical decision-making. The reports vary widely in their quality, which reflects the design of the study, the degree of rigour with which the research was performed, the ability of the authors to present the work in a format that enables accurate and complete appraisal, and the skills of peer reviewers and editors in appraising the submission. Readers must, therefore, develop their own skills when searching the medical literature, selecting and appraising the most

appropriate reports, and incorporating the best evidence into their clinical decisions and continuing education.

Levels of Evidence

The design of the study is the primary attribute of a report that influences the quality and level of evidence provided by that report. The design is important because it has the greatest influence on reducing bias and error in the findings noted. When producing a recommendation for clinical practice, whether it is for broader dissemination or for personal practice, the appraisal and incorporation of multiple reports has an important impact on the level of evidence that is assigned to that recommendation. Several schemes have been devised with the purpose of grading the evidence (Table 21-1). A grade should be assigned to any recommendation, and should influence the strength of that recommendation.⁴ Recommendations supported by high levels of evidence should carry the greatest weight in influencing clinical practice. The overall quality of evidence currently available regarding paediatric and congenital cardiac disease is somewhat low, given the paucity of randomised clinical trials, with the majority of recommendations being

TABLE 21-1

SYSTEM FOR GRADING THE QUALITY OF EVIDENCE AND STRENGTH OF RECOMMENDATIONS

EVIDENCE QUALITY FOR GRADES OF EVIDENCE		
Grade	Evidence	
A	Well-designed randomised, controlled trials or diagnostic studies performed on a population similar to the guideline's target population	
B	Randomised, controlled trials or diagnostic studies with minor limitations; genetic natural history studies; overwhelmingly consistent evidence from observational studies	
C	Observational studies (case-control and cohort design)	
D	Expert opinion, case reports, or reasoning from first principles (bench research or animal studies)	
DEFINITIONS FOR EVIDENCE-BASED STATEMENTS		
Statement Type	Definition	Implication
Strong recommendation	The reporter(s) believe that the benefits of the recommended approach clearly exceed the harms and that the quality of the supporting evidence is excellent (grade A or B). In some clearly defined circumstances, strong recommendations may be made on the basis of lesser evidence when high-quality evidence is impossible to obtain and the anticipated benefits clearly outweigh the harms.	Clinicians should follow a strong recommendation unless a clear and compelling rationale for an alternative approach is present.
Recommendation	The reporter(s) feel that the benefits exceed the harms but the quality of the evidence is not as strong (grade B or C). In some clearly defined circumstances, strong recommendations may be made on the basis of lesser evidence when high-quality evidence is impossible to obtain and the anticipated benefits clearly outweigh the harms.	Clinicians should generally follow a recommendation but remain alert to new information and sensitive to patient preferences.
Option	Either the quality of the evidence that exists is suspect (grade D) or well-performed studies (grade A, B or C) show little clear advantage to one approach versus another.	Clinicians should be flexible in their decision-making regarding appropriate practise, although they may set boundaries on alternatives; patient preference should have a substantial influencing role.
No recommendation	There is both a lack of pertinent evidence (grade D) and an unclear balance between benefits and harms.	Clinicians should feel little constraint in their decision-making and be alert to new published evidence that clarifies the balance of benefit versus harm; patient preference should have a substantial influencing role.

supported by expert or consensus opinion, themselves fraught with bias, or weak observational studies. Assigning grades to the evidence used when making recommendations, nonetheless, remains important, as it tempers their adoption, and highlights areas for further and more rigorous study.

Design of the Study

Not all types of study provide the same level of evidence, and not all studies should be evaluated in the same way.

Case Reports and Commentaries

These submissions provide the lowest level of evidence in the literature. They may be useful in identifying unique clinical observations. Case reports are often short communications, detailing either a single patient or a limited group of patients. While the literature was composed mostly of case reports in the first half of the previous century, today they account for only a small portion of all published studies. Their primary utility is potentially to highlight areas for further investigation, and increase awareness of possible rare variations and complications. They can also point to effective therapies, particularly if the patient described underwent multiple trials of a particular therapy, showing improvements when receiving the treatment, but suffering exacerbations when off the therapy.

Observational Studies

Observational studies are non-experimental in nature, whereby the phenomenon of interest is observed without imposing experimental or controlled conditions. They are highly variable regarding the quality and quantity of evidence they provide, and are fraught with potential bias and error. Carefully performed observational studies may be valuable in determining long-term outcomes and associated factors, in describing rare adverse events or rare disorders, and in determining the characteristics of diagnostic tests. Alternatively, hard-line proponents of evidence-based medicine will often reject offhand any type of observational study as inherently biased and of low validity. Previous studies have found that observational studies and randomised control trials often arrive at conflicting results about similar treatments.⁵

The designs of observational studies can be classified along several axes. First, they can be classified according to how they relate to a population. Studies using cohorts assemble a population either at risk for a given condition, or one that uniformly has a risk factor or condition. They may employ various strategies of sampling to reduce the number of subjects being studied, which ideally should be random. Case-control studies assemble a group of subjects with a given risk factor or condition, and a separate group of subjects without the risk factor or condition for the purposes of comparison. The validity of these studies rests largely on the representativeness of the chosen respective target populations. Ideally, the controls should be derived from the same general population as the cases. Second, observational studies can be classified as to the period of observation. Cross sectional studies examine subjects at a single point in time. Longitudinal studies follow subjects through time, tracking risk factors and outcomes. Third, observational studies can be classified as to the time when the measurements were made. Measurements can be made concurrently, meaning that they are made as the

investigation proceeds forward in time. This provides much better data, as it gives the investigator the opportunity to standardise definitions and methodology, and to apply measures for the control of quality. Measurements can be made non-concurrently, meaning that they were made in the past, and that the investigator is relying on recorded information. Abstractions from the medical records, and other uses of secondary data, constitute non-concurrent collection of data. This data may be of poor quality, since it would have been recorded by multiple individuals in a non-standardised manner, and collected for purposes other than addressing the research question at hand. The terms are also not mutually exclusive, in that collection of data for a given study may include both concurrent and non-concurrent elements. Fourth, observational studies can be classified according to their perspective regarding risk factors and outcomes. Studies that determine the state of a population in terms of risk factors, and then follow these factors forward in time to determine the development of outcomes, are referred to as being prospective in nature. Studies that determine the outcome for a population, and then trace it back to determine risk factors, are referred to as being retrospective in nature. These terms are almost exclusively used to describe studies of cohorts. The terms do not imply whether or not the collection of the data was concurrent or non-concurrent, and may not be mutually exclusive, since some observational studies identify a cohort of patients with a given condition, and then simultaneously collect data relating to risk factors and outcomes from the medical records. Many investigators erroneously describe non-concurrent collection of data as being retrospective in nature, when this may not be the case. When appraising a given report, it is important for the reader to be able to differentiate these various aspects of design, as they have important impacts on the validity and quality of the findings.

Cohort Studies

These studies are often employed to describe characteristics, management, and outcomes for a defined population. They can be solely descriptive in nature, or they can look for associations between characteristics and outcomes. Some of the characteristics may be factors in management. Since these factors are not randomly assigned, important bias is often introduced into any comparison of strategies for treatment, since the patients themselves, and other characteristics, often influence decisions regarding the selection of the treatment, which may also influence outcomes. These studies define the prognosis after different strategies for management have been applied to different cohorts of subjects. Several types of statistical adjustments are available to help minimise bias in these comparisons, but they are not uniformly applied, provide incomplete adjustment, and only adjust for characteristics known and measured by the investigators.

The first step in designing a cohort study is to define and assemble the cohort. The cohort must be relevant to the question at hand, and representative of the target population for which the investigator wishes to be able to extrapolate the results. Baseline demographic data are required. The study may be prospective in nature. The investigator would then measure predictive and potential confounding variables, and then follow the cohort forward in time, with tracking and assessments made to identify those subjects who develop outcomes. This design has advantages in that

multiple potential factors can be assessed at baseline with standardised measures, ensuring some control of quality. Risk factors can also be assessed dynamically, identifying those that are acquired over time, particularly those relating to management. In addition, multiple types of outcomes can be assessed dynamically. This type of design is useful for determining the incidence of outcomes, and for determining potential causal associations between risk factors and outcomes, albeit subject to the effects of potential confounding. The design is efficient if the prevalence of risk factors and outcomes is relatively common, and the time over which outcomes may occur is short. The design also allows the investigator to examine multiple outcomes. A prospective cohort may arise from a randomised clinical trial. After the analysis of primary and secondary outcomes related to the intervention being randomised, an analysis of the cohort may take place whereby factors associated with outcomes, other than the studied intervention, are sought. The quality of the data is usually excellent, although the problem of potential confounding still exists.

Studies of cohorts can also be retrospective in nature, in that a cohort is assembled, the outcome is determined, and then an assessment of risk factors is pursued, either in a cross sectional manner or through non-concurrent assessment of available sources of data, including recall of the subjects. These studies are useful in giving an estimate of the prevalence of outcomes and conditions. They are often more efficient than prospective studies, in that the cohort usually has been assembled and characterised in the past and the follow-up has occurred. The potential biases, however, are much greater, and the quality of the available data is suboptimal.

Cross Sectional Studies

Cross sectional studies are a type of study in which a cohort is assembled, and then all of the measurements are made at a single time in the present. They are useful for determining the prevalence of risk factors at a chosen point, and the outcomes in a population. Associations between risk factors and outcomes are sought, albeit that it is difficult to establish any causal relationships. Surveys are the most common methodology used for cross sectional studies.

Case-control Studies

Case-control studies are efficient designs for studying rare risk factors, or rare outcomes, for which study of a cohort would require an excessively large number of subjects, or an excessively long duration of follow-up. They are useful for generating hypotheses. They are most commonly retrospective in nature. A population of subjects with a given condition or outcome is assembled, and a comparison group is assembled from a much larger population known to be free of the given condition or outcomes. The two groups are then assessed for baseline characteristics and risk factors, usually from non-concurrent sources of data, sometimes including recall of the subjects. The relative frequency of risk factors is then determined in the cases compared to the controls. Since they are not population-based, these studies do not give estimates of prevalence or incidence, or relative risk.

The studies can be very efficient and cost-effective, but have many threats to their validity that are both difficult to control and detect. First, since the groups are differentiated on the basis of a single condition or outcome, this is the only outcome that can be assessed. Second, the selection of

both cases and controls can be challenging, and sampling bias and non-representativeness are important threats. It is often only prevalent cases that are represented, excluding subjects who died, or those whose condition resolved without detection, or those lost, and cases usually derive from a setting of medical care, this time excluding subjects with missed or incorrect diagnoses, or those who do not present for medical care, or present elsewhere. They may over-represent subjects with more symptomatic, severe, complex, or prolonged disease. The presence of a risk factor may influence the detection and inclusion of a case, which would cause the risk factor to be over-represented. Likewise, the selection of controls can be challenging. The goal ideally is randomly to select the controls from the larger population at risk from which the cases were derived. For convenience, controls can be recruited from the same setting in medical care. The controls would then be representative of the cases derived from the same catchment area. This might work if the setting is an outpatient clinic, and the controls are selected from those presenting for routine care. Controls derived from hospital-based populations are often presenting for care of their illness, which may falsely elevate the level of risk factors or confounding conditions. Controls can be derived from population-based samples from the same general population from which the cases were derived. This has the advantage in that a large number of potential controls are available. The population is defined either by geography or the medical catchment area, and controls are selected randomly. Additionally, they can be matched regarding important confounding characteristics, commonly age and sex, with the individual cases. This is a useful strategy when a known or highly suspect confounder has the potential for being differentially represented in the cases as opposed to the controls. A final strategy would be to have two or more control groups derived using different strategies or settings. Third, the nature of the assessment of risk factors is fraught with biases, particularly with regard to the potential for differential measurement in the cases versus the controls. This becomes increasingly important with greater subjectivity of the risk factors being assessed. Cases may be more likely to have certain measurements, the measurements may be made and recorded by more qualified observers, or the cases may be more motivated to recall certain factors. The investigators may be more aggressive in the pursuit of risk factors if they know that the subject is a case. Blinding of assessments wherever possible becomes important, wherein the assessment is occurring without the knowledge of whether the subject is a case or a control.

Nested Case-control Studies

A case-controlled study can be effectively nested within a cohort study. This increases efficiency and cost-effectiveness when assessment of a risk factor might be expensive or undesirable. When sufficient subjects have developed an outcome, which is usually rare, a sample of controls is selected from the subjects free of the given outcome within the cohort. The subjects chosen as controls may be matched to those representing cases according to key potential confounding characteristics, particularly time or period of observation. This allows the risk factor to be assessed in a smaller proportion of the cohort, usually from biological samples collected at a common baseline, or from a more intensive review of records.

TABLE 21-2

CRITERIONS FOR DEFINING CAUSALITY IN RELATIONSHIPS BETWEEN INDEPENDENT VARIABLES, INCLUDING MANAGEMENT, AND DEPENDENT VARIABLES, INCLUDING OUTCOMES OR CONDITIONS

- Is the relationship biologically plausible in terms of the current state of knowledge regarding pathophysiology?
- Is the relationship strong?
- Is the temporal relationship correct, in that the risk factor precedes the development of the outcome or condition?
- Is there evidence for a dose-response relationship?
- Is the relationship specific for the risk factor and outcome of interest?
- Is the relationship consistent across variations in study populations, settings and investigators, and design?
- Is the relationship free of known and potential confounding?
- Is the relationship free of systematic and random measurement error?
- If an intervention is successful in reducing or eliminating the risk factor, does this alter the outcome in a consistent and predicted manner?

Causality from Observational Studies

While associations between risk factors and outcomes can readily be determined from observational studies, the ideal is to identify those associations that are causal in nature, and free from bias, error, and confounding. There are several criterions that must be satisfied before concluding that a relationship is causal in nature, as outlined in Table 21-2. This becomes particularly important if the factor is a form of management.

Randomised Clinical Trials

Randomised control trials remain the gold standard for evaluation of the efficacy and safety of treatments or interventions. The principle of a randomised control trial is simple. A homogenous group of subjects is randomly assigned to an experimental arm or arms, or to a comparison arm or arms. Randomisation eliminates systematic differences at baseline between the groups. Any outcomes observed during the period of follow-up, therefore, should be attributable to the treatment alone, and not to underlying differences in subjects.

Randomised clinical trials provide the highest grade of evidence, particularly regarding establishing a causal relationship between an intervention and an outcome. This is for two primary reasons. First, randomisation provides the best chance that the groups chosen for study will be equivalent at baseline regarding both measured and unmeasured characteristics. Any differences would be attributed to chance or random error. The larger the population studied, the less likely random maldistributions are to occur. Random assignment must be truly random and tamperproof. Strategies can be used to ensure equal numbers of subjects in groups, so-called block randomisation, and to ensure key characteristics are equivalent in groups, this being stratified randomisation. When assessing the success of randomisation at the end of a trial by comparing measured characteristics at baseline, it is important to note clinically meaningful differences between groups, rather than statistically significant differences, the latter being dependent on the numbers of subjects. If the sample is large, small and unimportant differences may be statistically significant. If the sample is small, large and important differences may not be statistically significant.

The second feature of randomised clinical trials that contributes to providing evidence of high quality is the fact that all clinical trials rely on concurrently collected data. Thus, there is opportunity for standardisation of definitions, methodology, measurements and reporting, and implementation of measures for control of quality, such as adjudication. An important aspect of assessment is the concept of blinding, whereby the subjects, the investigators, and study personnel, and those analyzing the data, have no knowledge of the randomised assignment of the subjects. This ensures that the protocol is implemented identically in all groups, and is particularly important for assessments or outcomes that are more subjective in nature. For example, it is often surprising the number of subjects that will report hallucinations while taking an inert placebo. Additionally, even the most well-meaning assessors may interpret subjective tests differently if they think that they know the assignment of the subject. The blinding must be tamper-proof. It may not be feasible for some interventions to be blinded completely, such as a trial of surgical compared to transcatheter closure of septal defects, but as a minimum, measurements, assessments and analysis of the data can almost always remain blinded.

There are multiple phases in clinical trials depending on the amount of previous knowledge available on a specific intervention. Also, there are different types of clinical trials depending on the aim to be achieved. Clinical trials can be divided into four phases. Phase 1 trials establish the safety of the intervention, phase 2 trials establish a therapeutic effect, phase 3 trials compare the intervention to either a placebo or standard practice and establish relative benefit and risks, and phase 4 trials evaluate the long-term effects of an intervention.^{6,7} Prior to performing a clinical trial, it is important to determine which phase of the intervention the trial will represent, and what evidence is needed. The first and second phases are often small trials, using under 50 patients, and aimed at establishing safety and therapeutic effect. They are rarely reported in the literature, and rarely contribute to major changes in clinical practice. The third and fourth phases strive to compare the intervention with either the standard of care or a placebo, or non-intervention. These trials are most often reported in the literature, and are the driving force behind changes in clinical practice and development of guidelines. Investigators performing clinical trials have to respect the concept of equipoise, which states that patients cannot be deprived of care by receiving a placebo when a suitable alternative exists. Most randomised control trials aim to demonstrate that the new alternative is better than current standard of care. Some clinical trials, nonetheless, are aimed at establishing equivalence between the new intervention and the previous alternative. This type of trial is often conducted for the approval of generic drugs, and is called a non-inferiority trial.

Since the methodology for designing, performing, analyzing, and reporting of clinical trials is fairly standardised, this makes them easier to appraise. In the past 10 years, many biomedical journals have adopted the CONSORT guidelines for the report of clinical trials in the scientific literature.⁸

Meta-analyses

One criterion establishing causality is consistency of results from study to study. Before large-scale changes are made in clinical practice, a high level of certainty needs to be

achieved. In recent years, meta-analyses and systematic reviews have been conducted in order to pool data from multiple clinical studies. Meta-analyses identify a problem of interest and compile all studies, whether observational or randomised clinical trial, whether producing positive or negative results, and whether published or not, which have previously studied the issue at hand. Results from each study are then compiled, and a summary conclusion is achieved.^{9,10} Meta-analyses have many advantages, mainly to dilute the effect of studies with limited validities which might have inconsistent results. Statistical analysis of meta-analyses is highly complex and beyond the scope of this chapter. Peer-reviewed meta-analysis is published in the Cochrane Review, a repository of meta-analyses and systematic reviews, which is a high-quality reference on which to base changes in clinical practices. Unfortunately, few such meta-analyses are possible relevant to paediatric and congenital cardiac disease, given the paucity of clinical trials that are performed.

Critical Appraisal

Critical appraisal of published reports is an important activity, whether being pursued for the purpose of continuing education, or for the practice of an evidence-based approach to a clinical dilemma. Several guides are available for assisting with critical appraisal, with specifics depending on the perspective of the report being appraised. The *British Medical Journal* published a series of articles regarding specific methodology critically to assess the quality of different types of publications.^{11–18} Additionally, the *Journal of the American Medical Association* has published a series relevant to critical appraisal of the literature.^{19–25}

Critical appraisal begins by identification of the underlying question being addressed and the appropriateness of the design of the study. The quality of the design and its conduct is then assessed, in order to determine if the investigation has succeeded in achieving valid findings. The next step is to examine the findings to determine if they are both clinically important and relevant, and statistically significant. Finally, the report is appraised as to its relevance to personal practice or a specific clinical situation relevant to the reader. Critical appraisal can sometimes be challenging when the investigators do not provide sufficient information regarding various aspects of their study in their report.

Therapy

The reports of greatest interest to the clinician are those that report results of specific therapies. Those therapies may be aimed at producing a beneficial effect or at preventing an adverse outcome from occurring. Some reports are observational, and include only patients who receive a specific therapy. These studies are largely descriptive in nature, and may include an analysis for factors associated with observed outcomes. As such, these reports are about prognosis after a specific therapy. Some such observational studies may include a comparison group of an alternative therapy. These studies are weakest if the comparison group is largely historical, with the subjects accrued in a previous time period. If subjects are accrued similarly into the intervention groups throughout the period of study, but were not randomly assigned, then the report is a comparison of prognosis of two or more observational cohorts.

Appropriate statistical adjustment for measured factors will not completely account for differences related to the non-randomised assignment. The key feature that determines whether a report represents a valid study of therapy is random assignment of the intervention or interventions studied, as previously discussed. Critical appraisal can then proceed according to the questions outlined as follows:

Was the study conducted in manner that minimised bias?

Were the subjects randomly assigned to the study interventions?

- Was the randomisation strategy appropriate and tamperproof?
- Was randomisation successful, with measured baseline characteristics being equivalent for the study groups?
- If subjects were not randomly assigned or if randomisation did not succeed in producing equivalent groups, was appropriate statistical adjustment performed for differences in measured baseline characteristics and important potential confounding factors? Critical appraisal of non-randomised comparisons should be based on the guidelines for appraisal of a study dealing with prognosis.

Of those subjects randomised, what proportion in each group completed the study according to the protocol? It is important that all subjects be accounted for and that loss to follow-up be minimised. Studies where loss to follow-up occurs more frequently in one group versus the others may reflect an unanticipated effect of the intervention and bias comparisons regarding outcomes.

- What were the reasons for failure to complete the study, especially those related to study withdrawal and cross-over to an alternative group?
- Was the primary analysis based on the assignment at randomisation of the study subjects (that is, intention to treat analysis)? This type of analysis preserves the equal distribution of both measured and unmeasured characteristics between groups achieved by randomisation, and represents the most unbiased and hence valid comparison.
- What deviations from and violations of the study protocol were apparent, particularly premature, or temporary discontinuations of interventions?
- Was there evidence that the groups were treated differently, other than the randomised interventions, such as co-interventions? Co-interventions are additional interventions that may be necessary to manage effects of the primary intervention, and they have the potential to further influence outcomes and bias comparisons.

Was blinding as to study group feasible, attempted, and achieved for subjects, care providers, personnel, data analysts and investigators?

- If episodes of unblinding occurred, what was the level of unblinding and the reasons?
Were assessments conducted, evaluated, and interpreted in a rigorous and standardised manner?
- Was independent adjudication performed for key factors and outcomes, particularly those of a more subjective nature?

Are the results reported appropriately?

Are both absolute and relative differences in outcomes reported? If the outcome is dichotomous, then the absolute difference is the difference in the proportion

of subjects in each group who develop the outcome. The relative difference would be the absolute difference between the groups relative to the proportion in the comparison group.

Are confidence limits provided around differences?

Confidence limits are necessary to determine whether no difference has been reliably excluded, or if no difference is noted, whether a clinically important difference has been reliably excluded.

Are benefits interpreted in light of associated risks and adverse outcomes?

Are the results of sufficient magnitude and relevant?

Is the magnitude of the difference reported clinically important?

- Is the absolute benefit sufficiently clinically important to justify a change to the evaluated intervention in terms of relative costs, resources, risk of adverse effects, or outcomes?
- Is the number needed to treat to achieve or prevent an outcome provided, or is sufficient information given that it can be calculated, that is, the number of subjects needed to be treated relative to the alternative in order to achieve relative benefit for one subject? The number needed to be treated to achieve one beneficial outcome is calculated by taking the inverse of the absolute difference between groups in the proportion of subjects developing the outcome.
- Is the number needed to treat to achieve benefit offset by the presence of adverse effects or outcomes, or increased costs or resources, or is sufficient information given that it can be calculated, that is, the number of subjects who would have an adverse effect or outcome per subject with relative benefit?

Is there inordinate emphasis given to results from analyses of subgroups? Sometimes if the primary results of the clinical trial are negative, the investigators will attempt to determine whether there was a significant treatment effect in variously defined subgroup. While this type of analysis is important, it should not be viewed as definitive, and is a means for generating further hypotheses to be tested with additional studies.

Are the findings and implications of the report applicable to my own clinical practise?

Are the characteristics of the subjects studied, that is, inclusion and exclusion criteria and baseline characteristics, similar to those in my practise? For your patients for whom you would like to apply the intervention, you would expect them to meet the criteria for inclusion, and to have no criteria for exclusion, and to have characteristics similar to those reported.

Were all clinically important outcomes, particularly those most relevant to my patients, considered and assessed? If you are interested in using an intervention to have an impact on a particular outcome, you would expect that outcome to have been assessed and a benefit noted in the report. Alternatively, studies that fail to assess all relevant outcomes may note a benefit regarding a particular outcome but fail to note an adverse effect on other relevant outcomes that were not assessed, for which the balance of benefits versus risks would be tipped away from favoring the intervention.

Can the intervention be feasibly and practically applied within my practise?

Prognosis

This is the predominant type of report in the literature relating to paediatric and congenital cardiac disease. This mainly results from the fact that the conditions are rare, and that longer follow-up is required to detect relevant outcomes. Also, innovation in the field is occurring more rapidly than studies can be designed and implemented. The predominant factors being sought for association with outcomes are management factors, although such associations may be fraught with bias given the observational study designs. The predominant design is a cohort study, whereby the subjects have a common anatomical diagnosis or condition, or have undergone a specific type of intervention. The nature of the collection of data is usually non-concurrent, with the primary source being the medical record. The better studies have been prospective in nature with concurrent collection of data, and are often multi-institutional. The critical appraisal of such studies proceeds as follows:

Was the study conducted in manner that minimised bias?

Were the subjects that were studied representative of the larger population to which the investigators wish to extrapolate their results?

Did observation of the subjects start at a uniform point in time? Commonly, this represents the time of diagnosis, or the time that a specific intervention was performed. A common mistake is to start the period of observation at birth, rather than diagnosis. We do not know anything about the subject before they present and are diagnosed, and we cannot assume that we do. We also might erroneously assume that all subjects survive from birth to achieve diagnosis or intervention, which may not be the case. The situation becomes more complex with conditions that may be associated with a long pre-clinical period or with disease progression, such as hypertrophic cardiomyopathy or Marfan syndrome. If time of diagnosis is the starting point of observation, then there may be wide variation in age at diagnosis, which may be an important prognostic factor that needs to be explored. If the starting point is a diagnosis, then careful and objective definitions of that diagnosis need to be reported.

Were the subjects followed sufficiently long for the outcomes of interest to occur with sufficient frequency? If survival after diagnosis or an intervention is achieved, it may take many years before there is recurrence of disease or important complications arise.

Were all of the subjects followed completely? Subjects may become lost to follow-up for reasons that are related to their diagnosis, intervention, or outcomes that develop. Failure to account for these subjects may bias estimates of prognosis and associated factors.

Were outcomes and potential associated factors measured uniformly, objectively, and in an unbiased manner?

In defining the prognosis or comparing the prognosis for different diagnoses or interventions, was adjustment appropriately made for potential important prognostic factors?

Are the results reported and interpreted appropriately?

Was the correct methodology used in presenting the outcomes of interest?

- For time-related outcomes or events, were appropriate methods used to account for the time-relatedness of these data? Likewise, special analytic techniques are required to handle events that may be repeated, or to handle different mutually exclusive events that may compete with one another.
- For outcomes that evolve over time, were appropriate methods used to account for serial measures within individuals and changes in magnitude?

Was the correct methodology used to determine associations between outcomes and potential associated factors? Unless the number of subjects is extraordinarily small or the outcomes are very infrequent, some sort of multi-variable analysis should be performed.

Are the results reported with confidence intervals, or at least measures of variation, particularly when differences relevant to a particular factor are being reported?

Do the associated factors change over time? Does the magnitude of the association with outcome change over time? Do new factors emerge while others become less relevant? Do the factors themselves change over time?

Are the results of sufficient magnitude and relevant?

What is the magnitude and nature of risk of the outcome? Outcomes that are frequent and of greater clinical importance are of more interest. The nature of the risk of an outcome can be particularly of interest. Does the risk of the outcome change over time, indicating high-risk periods? Are there periods of stability followed by rapid progression?

How strong are the factors associated with the outcomes? This is particularly evident if a strong dose-response relationship is noted, whereby a small increment in a factor is associated with a greatly increased likelihood of the outcome. Threshold effects should be sought.

Are the findings and implications of the report applicable to my own clinical practise?

Do my patients meet the entry criteria described in the report, and do they have similar characteristics to the study subjects?

Are the results such that they provide valid and important information regarding counseling about prognosis for my patients?

Are the results such that they would alter patient management in the presence of associated factors reported?

This might lead to the pursuit of alternative therapy that might provide a better prognosis or prevent certain outcomes. It might also lead to the monitoring of selected patients more closely who have certain associated factors. Interventions might be directed specifically at treating or preventing certain associated factors if they were shown to have sufficient evidence of a causal association with the outcome.

Harm

Some reports focus on adverse effects or events related to a given exposure or intervention. These types of reports are much less common in the literature pertaining to paediatric and congenital cardiac disease. Nearly all types of study can give evidence regarding the relationship between an adverse outcome and a given factor, and critical appraisal of the report necessarily must take into account aspects

of the design in the evaluation. A specific example might be a report addressing the question, 'What is the risk of congenital cardiac disease in offspring of mothers taking blockers of angiotensin receptors during pregnancy?' A randomised clinical trial could be designed to address this question, but would be difficult to perform, given concerns about feasibility and ethical issues. This would, however, give the strongest evidence in support of a causal relationship. Alternatively, a cohort study might be used whereby all pregnant mothers are enrolled shortly after conception, taking note of history of medication, and its use during pregnancy, and screening all fetuses and neonates for congenital cardiac disease. The outcomes of pregnancies of mothers taking blockers would be compared to those of pregnancies where the mothers took either no or different medications. This would necessarily have to involve huge numbers of pregnancies, since the proportion of mothers taking a blocker, and the proportion of fetuses and neonates who have a congenital cardiac defect, would both be expected to be very low. The design might work well for factors and adverse outcomes that are more prevalent and are evident after only a short period of follow-up. The key measure would be the relative risk, or the ratio of the risk of development of congenital cardiac disease for the offspring of mothers taking a blocker of angiotensin receptors versus the risk for offspring of mothers not taking any medication. In this case, the most efficient design would be a case-control study that is prospective in nature, whereby a group of pregnant mothers were enrolled who were taking a blocker and were matched on key characteristics to a group of mothers who were taking no medications. The two groups would then be followed and assessed as to the proportion of fetuses and neonates who develop congenital cardiac defects. The study would potentially have the bias inherent to the case-control study design, predominantly the adequacy of selection of both the cases and the controls. The key measure would be the odds ratio, or the ratio of the odds of development of congenital cardiac disease for the offspring of mothers taking the blocker versus the odds for offspring of mothers not taking any medication. When the exposure or risk factor is not dichotomous in nature, relative risk and odds ratios may be expressed as the increase in the ratio for a given increment increase in the magnitude of the risk factor. More complex measures of association are required when the outcome is not dichotomous, or when the outcome is a time-related event. The critical appraisal of studies of harm proceeds as follows:

Was the study conducted in manner that minimised bias?

Was a comparison group without the exposure or factor of interest clearly identified and similar regarding other important factors that might influence outcome?

Were assessments of both the exposure or factor and the relevant outcomes conducted and interpreted in an identical manner irrespective of the exposure status of the subject?

Was follow-up sufficiently long and complete in order to ensure development and ascertainment of outcomes?

Was the study design such that there was a correct temporal relationship between the exposure and subsequent development of the outcome? This is one of the criteria that contribute to assurances that the association is causal in a nature.

Is there evidence that a dose-response relationship exists between the magnitude of the exposure or factor and the subsequent development and magnitude of the outcome? Again, another criterion that implies a causal nature to the observed association.

Are the results reported and interpreted appropriately?

Are the measures of association reported appropriate for the study design and the level of measurement of the exposure or factor and the outcome?

Are confidence intervals provided for all measures of association?

Are the results of sufficient magnitude and relevant?

Is the observed association strong?

Are observed measures of association sufficiently reliable?

- Are the confidence intervals sufficiently narrow?
- Do the confidence intervals include values that would indicate no association?
- If the observed association is weak or in the wrong direction, implying a decreased risk of the outcome related to the exposure, do the confidence intervals exclude a clinically important positive association?

Are the findings and implications of the report applicable to my own clinical practise?

Do my patients meet the entry criteria described in the report, and do they have similar characteristics to the study subjects?

Are the results such that they provide valid and important information regarding counseling about prognosis for my patients should they have the exposure or factor?

Is the association of sufficient magnitude that it would alter management? This might lead to reduction or eliminations of the exposure or factor. It might also lead to monitoring selected patients more closely who have the exposure or factor. It also might lead to additional therapies aimed at neutralising causal pathways attributable to the exposure or factor if it could not be avoided.

Diagnosis

The clinical practise of those involved with paediatric and congenital cardiac disease relies heavily on diagnostic testing, primarily imaging. A good diagnostic test is valid, reliable, quick, safe, simple, associated with minimal discomfort, inexpensive and ethical. Studies about optimal and novel methods for making measurements are common, often in comparison with an accepted methodology. These studies of comparison often do not relate the methods to a standard criterion, and it is difficult to determine which method is better when the analysis shows only differences between the two methods. In addition, measures of association are often used, when in fact we are more interested in measures of agreement. Other studies aim to look at the contribution of new tests to the definition of clinical conditions and their prognosis or response to treatments, such as defining the relationship of brain natriuretic peptide levels in relation to clinical markers of heart failure. For these studies, measures of association are appropriate.

The classic study of a diagnostic test is one designed to determine the performance characteristics of a given test in making or excluding a specific diagnosis. These studies are much less prevalent. The methodology also applies to studies about screening. We are interested in the accuracy of the

methods themselves, particularly if they require subjective assessment. We wish to know features such as test-retest reliability, and intra- and inter-observer variability. Test-retest reliability is the amount of variation in pairs of measurements performed in the same individuals under the same conditions by the same observers but at different times. It represents variation of the test itself together with intra-individual variation. Intra-observer variability is the amount of variation when the same observer performs or interprets the same test in the same individual at the same point in time. Inter-observer variability is the amount of variation when two or more different observers perform or interpret the same test in the same individual at the same point in time. Each of these is defined by determining the degree and pattern of agreement, not correlation or association.

In relation to defining or excluding a diagnosis, we wish to know the performance characteristics of the test itself in both subjects with and without the disease or condition of interest as defined by application of a criterion standard. Sensitivity is the ability of the test to accurately identify those subjects with the disease. It is the proportion of subjects with the disease, the denominator, who would have a positive test result and be identified, the numerator. The remaining proportion would represent those subjects with missed disease. Specificity is the ability of the test to accurately exclude the diagnosis in those who do not have the disease. It is the proportion of subjects who do not have the disease, the denominator, who would have a negative test result, the numerator. The remaining proportion would represent those subjects who would be incorrectly identified as having the disease, or false positives. These subjects would either be incorrectly labeled and managed for the condition, or may require further confirmatory testing. For tests which give a result which is a continuous measure, one can calculate the sensitivity and specificity using as cut-points all values of the variable, and plot a receiver-operating characteristic curve. This curve plots sensitivity on the y-axis and the proportion of false positives on the x-axis. A plot that results in a diagonal line running from the bottom left to the upper right corner represents a test that has no discriminatory ability. Plots that are curves towards the upper left corner show greater discrimination the closer they get to that corner. Alternatively, one can plot the area under the curve as a proportion. The closer the proportion of area under the curve is to 1, the more perfect the discrimination of the test. The test value with the sensitivity and proportion of false positives that comes closest to the upper left corner is the value that has the best discriminatory performance, and may be used as a cut-point.

Additionally, it is possible to calculate an entity called the likelihood ratio associated with a particular result. The likelihood ratio associated with a positive test result would be the ratio of the proportion of subjects with the disease who would have a positive test result, the numerator and its sensitivity, divided by the proportion of subjects without the disease who would have a positive test result, the denominator and the false positives. The likelihood ratio associated with a negative test result would be the ratio of the proportion of subjects with the disease who would have a negative test result, the numerator or missed disease, divided by the proportion of subjects without the disease who would have a negative test result, this representing the denominator and specificity. Likelihood

ratios of 1 represent tests with no ability to differentiate those with versus without the disease. Increasingly larger or smaller likelihood ratios indicate increasing performance of the test. These performance characteristics can be determined from a case-control study, or from a cohort study where all members of the cohort have had their disease status defined using the standard criterion. For rare diseases, the case-control design is more efficient, but may be biased in terms of the representativeness of the cases and the controls. These characteristics are fixed, and do not change when the test is applied to different populations.

We are also interested in the performance of the test under different clinical situations when applied to cohorts of subjects, particularly where the prevalence of the disease in the cohort or the probability of disease in the individual before application of the test can be estimated. This can only be determined from cohort studies where the criterion is uniformly applied to determine the prevalence of disease. Two performance characteristics are highly influenced by the prevalence of the disease in the population being tested. Positive predictive value is the proportion of subjects who have a positive test result, the denominator, with those having the disease representing the numerator. The remaining proportion would represent false positives. Negative predictive value is the proportion of subjects with a negative test result, the denominator, with those who do not have the disease being the numerator. The remaining proportion would represent missed disease. Alternatively, likelihood ratios can be used to determine the performance of the test in different cohorts or individuals where the likelihood of disease varies. If one can estimate the likelihood of disease before applying the test, this being the pre-test probability, the likelihood ratio can be applied based on the results of the test to a nomogram (Fig. 21-1) to determine the likelihood of disease in the subject given the test result, or the post-test probability.²⁶

The critical appraisal of studies of diagnosis proceeds as follows:

Was the study conducted in manner that minimised bias?

Were a criterion and the test uniformly both applied to all subjects in an independent and blinded manner?

It is important that knowledge of the disease status of the subject does not influence a decision to perform the test or influence its interpretation. Likewise, all subjects should be assessed as to the state of their disease. This should occur independently of performance of the test, and without knowledge of the results.

If the design is a cohort study, does the cohort include sufficient subjects with the disease at appropriate stages for which the test might be applied for screening or diagnosis in clinical practise?

If the design is a case-control study, are the cases and controls representative of the cohort to whom the test might be applied in clinical practise?

Are the methods by which the test was performed described in sufficient detail that they can be replicated in clinical practise?

- Are the sources of variability assessed or described, such as test-retest reliability, and intra- and inter-observer variability?

Figure 21-1 The nomogram is designed to interpret the results of diagnostic tests using likelihood ratios and incorporating the pre-test probability to determine the post-test probability of the condition or disease. To use the nomogram, locate the relevant pre-test probability on the line on the left and the likelihood ratio appropriate for the test result from the middle line. Connect these two points and extrapolate the line until it intersects the line on the right, and note the corresponding post-test probability. (From Fagan TJ: Nomogram for Bayes theorem [Letter]. *N Engl J Med* 1975;293:257.)

- What control measures were in place to reduce variability and ensure accuracy?
- Are the results reported and interpreted appropriately?
- Are performance characteristics, such as sensitivity and specificity reported, with appropriate confidence limits?
 - Are likelihood ratios reported, or are sufficient data provided that they might be calculated?
- Are the results of sufficient magnitude and relevant?
- Are there performance characteristics of the test, such as sensitivity, specificity, and likelihood ratios, sufficient that both missed disease and false-positive diagnoses will be minimised?
 - If the design is a cohort study, what is the magnitude of missed disease and false-positive diagnoses for this cohort, and the potential implications of such?
- Are the findings and implications of the report applicable to my own clinical practise?
- Is it feasible and achievable to incorporate the testing procedure into my own clinical practice?
- Can the test be performed in my clinical practise with sufficient reliability and accuracy, and the results obtained in a timely and efficient manner?
 - Are there acceptability or ethical issues which might preclude the patient from allowing the test to be performed? Are there undue discomforts or adverse effects?
 - Would the results of the test be applicable to the diagnostic dilemmas and patients in my clinical practise?
 - If applicable, would the results be sufficient or contribute to decisions regarding further investigation or management?
 - If applied, would the results of the test be of benefit to my patients?
 - Would knowledge of the state of the disease lead to interventions that would optimise outcomes?
 - Would knowledge of the state of the disease contribute to beneficial behavioural changes in my patients?

Incorporating Evidence into Clinical Practise

Evidence is incorporated into clinical decision-making through the practise of evidence-based medicine. This is broadly defined as the integration of the best available research with clinical expertise taking into account the preferences for therapies and outcomes of patients. Although the roots of evidence-based medicine derive from a trend established in the early 1800s to have medicine driven by science, it has been developed and elevated to a higher level in the past few years with the increase in the number of available therapeutic options. Additional factors include the escalation in costs associated with the introduction of new technologies into routine medical practises. Before implementing widespread changes in clinical practise, especially when those changes may be associated with higher costs yet benefit fewer patients, health care managers and providers increasingly demand a much higher level of evidence regarding their relative efficacy and safety. It is clear that the era of evidence-based medicine is just starting and that the clinical practice of the future will need to be based on valid evidence, even in the absence of randomised control trials.²⁷

There is a real concern among some in the medical field that the blind use of evidence-based medicine in clinical practise might lead to a cookbook approach to clinical practise. From the beginning, nonetheless, evidence-based medicine has been defined as the integration of the highest level of evidence about medicine with clinical expertise and patients' values. The practice of evidence-based medicine must consider and incorporate the beliefs, values and preferences of an individual patient, as well as consideration of the local resources, expertise and outcomes and the unique characteristics and circumstances of that patient. It does imply that clinical decisions must be based on sound science and research.

In most clinical situations, the process of evidence-based medicine is started by the building and critical appraisal of a body of evidence relevant to a specific clinical question or dilemma. Drafting of the question, specifically as a question and not as a topic or a statement, is an essential first step that will guide the search strategy for relevant and applicable research evidence. Questions that seek general knowledge about a disorder or condition are less relevant for this process than questions which relate to specific clinical dilemmas, usually arising from uncertainties in clinical decision-making around specific cases. Questions that are more specific and include more elements relevant to the clinical dilemma are desired. These specific components can then be incorporated into search terms and limits. Textbooks, unless they are research-evidence-based and updated in real time, are poor sources of evidence. Searchable databases of either evidence reviews or the medical literature are preferred. Retrieved reports can be scanned as to their relevance to the specific question at hand, and the nature and degree of rigour of the study design or evidence review. Greater weight is given to studies which are valid, reliable and accurate. It is usually necessary to include only one or two reports in the process of critical appraisal. Based on the appraisal, the decision is made as to whether the findings are sufficiently valid and important that a preliminary answer or decision may be supported. Consideration is then given as to how the answer or clinical decision supported by the evidence might be mediated by clinical expertise and patient characteristics and preferences. The process should be evaluated and recorded for future reference, and updated with the addition of new research evidence and greater clinical experience. As such, these steps integrate the process directly into clinical care (Table 21-3).

TABLE 21-3

STEPS IN THE PRACTISE OF EVIDENCE-BASED MEDICINE

- Convert information needs usually relevant to a clinical question or dilemma into answerable questions.
- Search for the best evidence usually through searchable databases of published reports with which to answer the question.
- Critically appraise the evidence for its validity, the importance and reliability of the findings and the applicability to the general clinical question or dilemma at hand.
- Evaluate, record and archive the previous steps for the purposes of future use and to allow integration of new evidence as it arises.

ANNOTATED REFERENCES

Books

- Straus SE, Richardson WS, Glasziou P, Haynes RB: Evidence-Based Medicine: How to Practice and Teach EBM, 3rd ed. Edinburgh: Churchill Livingstone, 2005.
This book provides clear explanations of the primary steps in the practise of evidence-based medicine, including how to ask answerable clinical questions, how to translate them into effective searches for the best evidence, how critically to appraise that evidence for its validity and importance, and how to integrate it with patients' values and preferences.
- Hall GM: How to Write a Paper, 4th ed. London: BMJ Books, 2008.
This concise book provides clear instructions on getting reports published in biomedical journals and covers all aspects of writing each section of a structured paper, incorporating the latest information on open access, electronic publication, and submission.
- Elwood M: Critical Appraisal of Epidemiological Studies and Clinical Trials, 3rd ed. New York: Oxford University Press, 2007.
This book presents a logical system for critical appraisal, and helps readers evaluate studies and carry out their own studies more effectively. It is applicable to a wide range of issues, and to both intervention trials and observational studies.
- Altman DG: Practical Statistics for Medical Research. London: Chapman & Hall/CRC, 1990.
This is a problem-based textbook for those who need to use statistics but have no specialised mathematics background. It provides clear explanations of key statistical concepts, with a firm emphasis on practical aspects of designing and analysing medical research. Special attention is given to the presentation and interpretation of results and the many real problems that arise in medical research.
- Hulley SB, Cummings SR, Browner WS, et al: Designing Clinical Research, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2006.
This book is an excellent practical guide to planning, tabulating, formulating, and implementing clinical research, with an easy-to-read, uncomplicated presentation. The book explains how to choose well-focused research questions, and details the steps through all the elements of study design, data collection, quality assurance, and basic grant-writing.
- Norman GR, Streiner DL: Biostatistics: The Bare Essentials, 3rd ed. Toronto: BC Decker, 2008.
Free of calculations and jargon, this book speaks so plainly that you will not need a technical dictionary. The principles of probability and statistical tests, and their use, are explained simply and clearly with a sense of humour. Throughout the guide, areas in which researchers misuse or misinterpret statistical tests are highlighted.

- Silverman WA: Where's the Evidence? Debates in Modern Medicine. New York: Oxford University Press USA, 1999.

The author asks us to consider whether the preoccupation of institutional review boards with informed consent makes sense without a parallel requirement that the scientific design of the research be valid, and the question that it asks be worthwhile. The commentaries cover a multiplicity of topics, from observer bias to sampling and representativeness, from eugenics to euthanasia, from information overload to random assignment.

- Lang RA, Secic M (eds): How to Report Statistics in Medicine: Annotated Guidelines for Authors, Editors, and Reviewers, 2nd ed. Philadelphia: American College of Physicians, 2006.

This book presents a comprehensive and comprehensible set of guidelines for reporting the statistical analyses and research designs and activities commonly used in biomedical research.

Isomerism of the Atrial Appendages

STEVEN A. WEBBER, HIDEKI UEMURA, and ROBERT H. ANDERSON

It has long been recognised that congenital absence of the spleen, or the presence of multiple spleens, is associated with severe congenital malformations of the heart.¹⁻³ Some of the most complex forms of congenital cardiac disease are associated with these splenic abnormalities, and the prognosis for many patients with these lesions remains poor, even in the modern era of congenital cardiovascular surgery. If progress is to continue in the care of these children, the cardiac abnormalities need to be determined with precision in each case, and their nature be conveyed in unambiguous fashion to the surgeon attempting correction or palliation. Description of the cardiac malformations found in association with splenic abnormalities, however, has been the cause of much confusion and controversy. It is now established that cardiac structures are best identified on the basis of their most constant components, following the so-called morphological method.⁴ When considering the atriums, it is the appendage which is most constantly present (see Chapter 1). It is then the presence of isomeric atrial appendages that is the most accurate feature with which to stratify the patients previously labeled as having splenic syndromes,⁵ or more recently as having visceral heterotaxy.⁶⁻⁸ In the first part of this chapter, we review some of the historical landmarks in the recognition of the cardiac malformations seen in the presence of isomeric atrial appendages, and attempt to clarify some of the confusing nomenclature that has evolved over the last few decades. Subsequently, we describe in detail the morphological and clinical features of these cardiac malformations. We then focus attention on the progress made in recent years in the diagnosis and surgical treatment of these generally highly complex malformations.

HISTORICAL NOTES AND DEFINITIONS

Absence of the spleen is an obvious autopsy finding, which is unlikely to be missed, being noted as long ago as the 16th century, but very likely then as the consequence of tuberculous infection. The earliest recorded examples of congenital absence of the spleen are probably those appearing in 1826.² Multiple spleens occurring as a congenital malformation had been recorded more than 30 years previously.¹ These early accounts recognised not only the splenic anomalies, but also abnormal arrangements of other organs, as well as the cardiac malformations. Over the last five decades, there has been a more systematic analysis of the cardiac and extracardiac malformations seen in patients with congenital splenic anomalies. This has resulted in recognition that the entire bodily arrangement of patients, now often described as visceral heterotaxy,⁶⁻⁸

differs from the usual arrangement, or situs solitus, and also from the mirror-imaged variant, typically described as situs inversus. Those observing the abnormal arrangement of the abdominal organs^{3,9} had noted the association with congenital cardiac disease. They had also noted the symmetrical nature of the lungs. Ivemark, in his classical description, introduced the phrase 'asplenia, a teratologic syndrome of visceral symmetry'.³ Putschar and Mannion,⁹ with remarkable prescience, stated: 'The relationship of agenesis of the spleen to disturbed development of laterality, however, goes beyond the manifestations of obvious situs inversus. Between the normal situs, which is asymmetrical, and the situs inversus, which is the asymmetrical mirror-image of normality, a symmetrical situs sometimes exists, exhibiting symmetrical rightness or leftness on both sides'. It is hard to find any subsequent account that so well expresses the concept of biological isomerism, namely, lack of normal lateralisation leading to visceral symmetry.

Others had also emphasised this symmetry, with note taken of isomerism of the right atrial appendages and sinus nodes in patients having absence of the spleen,¹⁰ and bilateral left-sidedness in patients with multiple spleens.¹¹ Despite such long-standing recognition of isomerism of the organs and atriums as the essence of these malformations, others had argued that the concept of isomerism had no scientific foundation,¹² and continued to stratify the cardiac malformations found in these settings under the headings of asplenia and polysplenia, grouping them together as situs ambiguus.¹³ This approach is less than ideal at a time when most centres dealing with congenital cardiac disease use a sequential segmental approach to diagnosis, a form of analysis which must start with accurate identification of the arrangement of the atrial chambers. When the essence of the malformations is isomerism, rather than lateralisation, of the atrial appendages, there is nothing ambiguous, or uncertain, concerning the atrial morphology. In terms of the scientific rigour, it is also the case that molecular advances have made it possible to generate knock-out mice with unequivocal isomerism of the atrial appendages.¹⁴ We urge strongly, therefore, that the term situs ambiguus be abandoned, even though a definition for the entity was suggested by the International Working Group dealing with nomenclature.⁷

We find it difficult to understand why so many authors continued to use the terms asplenia and polysplenia to characterise the congenital anomalies of this group of patients. For the cardiologist, it is hard to believe that knowledge of the state of the spleen, even recognising the risk of overwhelming sepsis in its absence, takes precedence over precise description of the complex cardiac malformations.

When the cardiac malformations were first emphasised as a feature of patients having congenital absence of the spleen, a sequential segmental approach to the description of congenitally malformed hearts had yet to be developed. At that time, a short, but limited, diagnostic label, such as asplenia syndrome, sufficed to describe a condition then considered prognostically hopeless. These labels now surely seem obsolete for the fundamental description of the complex cardiac malformations associated with abnormalities of lateralisation. Furthermore, discordance between splenic status and the arrangement of the atrial appendages is far from rare.⁵ The first step in the sequential diagnosis of any patient suspected of having congenital cardiac disease is now the identification of bodily and atrial arrangement, irrespective of the state of the spleen. This should be followed by a systematic description of the cardiac malformations, using the principles of sequential segmental analysis (see Chapter 1). This approach can include description of the state of the spleen, when pertinent, and listing of other extracardiac anomalies. It simply emphasises that analysis starts within the heart, and is based on the arrangement of the atrial appendages.

As we have already discussed, the background to some of the more complex and confusing terminology used previously to describe the hearts and organs of patients with isomeric atrial appendages was reviewed in the recent report from the International Nomenclature Group.⁷ In this respect, it should be noted that the term isomerism has been widely accepted as short-hand for the overall description of hearts with isomeric atrial appendages. The atriums themselves, of course, are not literally isomeric, nor are the appendages identical in all respects. Both atrial appendages, in the setting of visceral heterotaxy, nonetheless, have morphologic features characteristic of either the typical right or left structures. It is this feature that should be used to stratify the syndrome when assessing its cardiac aspects.

ANATOMY

Atrial Anatomy

Structural isomerism, strictly enantiomerism, is seen when entities are mirror-images of each other (Fig. 22-1). In this respect, the usual arrangement of the organs within the body, when compared to its mirror-imaged variant, represents biological enantiomerism (Fig. 22-2). As applied to those with visceral heterotaxy, however, the concept of isomerism implies that the mirror-imaged structures are present in

Figure 22-1 The objects shown are mirror images of each other. This is the essence of structural isomerism, properly described as enantiomerism.

Figure 22-2 The cartoons show the essence of the usual body arrangement (left), and its mirror image (right). Individuals with these arrangements would exhibit enantiomerism relative to each other.

the same individual (Fig. 22-3). Within the heart, it is the atrial appendages, when assessed according to the extent of the pectinate muscles relative to the atrioventricular junctions,⁶ which show the enantiomeric features. It should not be thought that the hearts from patients having isomeric right atrial appendages also exhibit bilateral superior and inferior caval veins, along with a coronary sinus draining to each atrium. As we will see, absence of the coronary sinus is a defining feature of those having isomeric right atrial appendages. Nor do hearts with left atrial appendages bilaterally have two normal left atriums, each receiving four pulmonary veins. The presence of isomerism within the atrial segment simply means that there is duplication of those parts of the appendages exhibiting the characteristic anatomical features of rightness or leftness. Emphasis is placed on the appendages because venous connections, vestibular morphology, and septal structure are all variable. For example, the pulmonary veins may be connected to the morphologically right atrium, or to an extracardiac site (see Chapter 24). The atrioventricular junction may be absent, as in tricuspid or mitral atresia. Although the atrial

Figure 22-3 The cartoons show the typical bodily arrangements in the setting of visceral heterotaxy. In each instance, insofar as the thoracic structures are concerned and the atrial appendages, the right and left sides are mirror images of each other, hence, enantiomeric. This is the essence of bodily isomerism.

septum has typical morphologically right and morphologically left sides, it is not always there. These variable features, therefore, following the precepts established in the morphological method,⁴ cannot be used as reliable indicators of morphologically rightness or leftness. Instead, the heart with right isomerism will be characterised by the presence of appendages each having the morphology of the normal right appendage. The uniformly characteristic feature of rightness is the extent of the pectinate muscles around the atrioventricular junctions, so that they meet at the crux (Fig. 22-4). In contrast, in the heart showing left isomerism, each of the appendages will have the characteristic morphology of the normal left appendage, with the pectinate muscles contained within the tubular appendages, the posterior vestibular areas being smooth on both sides, and directly confluent with the venous components (Fig. 22-5). The major morphological features of rightness of the isomeric appendages, as shown in Figure 22-4, are to be found internally. External features are also usually distinctive. In most hearts, each triangular appendage is separated along its entire border with the smooth-walled part of the atrium by an extensive groove, marked internally by a prominent terminal crest (Fig. 22-6). Although seen in most cases, this feature is not universally present. Similarly, the external shape of the appendages is usually but not constantly characteristic. Morphologically right appendages are almost always triangular, but the triangle can have a narrow base. It is the extent of the pectinate muscles which is the universal criterion for morphologically rightness on both sides of the atriums (see Fig. 22-4).

We have usually found it possible, when examining hearts from patients with left isomerism, to recognise morphologically left appendages bilaterally because of their narrow shape, along with their constricted junction with

Figure 22-4 The atrial roof is reflected superiorly to show the common atrioventricular (AV) junction in this heart from a patient with visceral heterotaxy. The pectinate muscles encircle the common junction on both sides, meeting at the crux (arrows). This is the essence of isomerism of the right atrial appendages. Note the septal strand.

Figure 22-5 Like the heart shown in Figure 22-4, this specimen comes from a patient with visceral heterotaxy. There is again a common atrioventricular (AV) junction, and a common atrium. In this specimen, however, the pectinate muscles are confined within the tubular appendages, the vestibules being smooth at the crux on both sides (arrows). This is the essence of isomerism of the morphologically left appendages. LSCV, left superior caval vein; RSCV, right superior caval vein.

the smooth-walled atrial portions (Fig. 22-7). It is the internal characteristics which have again proved to be constant (see Fig. 22-5). Although the pectinate ridges may extend more laterally than the constricted junction of appendage and atrium, they are always significantly more limited in their extent than in the morphologically right atrium (compare Figs. 22-4 and 22-5). Using the criterion of the extent of the pectinate muscles, we have found it possible uniformly to distinguish morphologically right from left appendages, thus permitting the distinction of isomeric and lateralised arrangements, even when we studied each individual atrium in isolation.⁶

The arrangement of the appendages in patients with visceral heterotaxy is usually, but not universally, harmonious with the arrangement of the thoracic organs. Discordance between thoracic and atrial arrangement can also be found in patients with normal hearts, typically in the syndrome of biliary atresia with multiple spleens, bronchial isomerism, but usual atrial arrangement.^{15,16} We discuss this discordance, and the arrangement of the other systems of organs, in greater detail in the sections that follow.

Venoatrial Connections

Anomalous venoatrial connections are the rule in patients with isomeric atrial appendages. Although a small proportion of cases have an overall pattern of drainage which can be considered usual, or mirror-imaged, even in these hearts the patterns are never morphologically normal. In each individual, any pattern must be anticipated, but certain features are sufficiently common to permit the differentiation of right and left isomerism. It is the connection of the pulmonary veins which is most reliable in permitting this distinction. In right isomerism, because the pectinate

Figure 22-6 The triangular appendages (*stars*) on the right (A) and left (B) sides in a patient with right isomerism. Note the bilateral superior caval veins (SCV) and the pulmonary veins coming together in a mid-line confluence. The yellow dots show the bilateral terminal grooves. ICV, inferior caval vein.

Figure 22-7 The atrial appendages (*stars*) to the right (A) and left (B) sides of a patient with visceral heterotaxy. It is easy in this instance to recognise that both are morphologically left simply from their external appearance. Note the bilateral superior caval veins (SCV).

muscles extend to the crux on both sides, the pulmonary venous connections are always anatomically abnormal. Even when all the pulmonary veins connect to one of the morphologically right atrial chambers, be the chamber right- or left-sided, the anatomy is abnormal when compared to the normal connections of the pulmonary veins to the morphologically left atrium. This is because the morphologically left atrium never exhibits pectinate muscles

extending to the crux (Fig. 22-8). Most usually, if the pulmonary veins do return to the heart, they make their connection via a fibrous confluence, typically opening centrally (Fig. 22-9). When there are morphologically right appendages bilaterally, therefore, the connections of the pulmonary veins will always be anomalous anatomically, even if the atrium receiving the veins is itself left-sided.

Figure 22-8 In this heart, all the pulmonary veins return to the right-sided atrium, which has an appendage of right morphology. In anatomical terms, this is totally anomalous pulmonary venous connection. Note the absence of the coronary sinus.

Figure 22-9 In this patient with bilateral appendages of right morphology (note the pectinate muscles extending to the crux on both sides), the pulmonary veins drain through a central fibrous confluence. This is anatomically anomalous.

In about half the patients having isomeric right appendages, such semantic pitfalls do not arise, because the pulmonary venous drainage is exclusively to an extracardiac source. The site of anomalous connection is then as varied as when totally anomalous pulmonary venous connection is seen with usual atrial arrangement (see Chapter 24). The problems of obstruction within the anomalous pulmonary venous pathway are the same. Indeed, clinical experience suggests that an obstructed supracardiac pathway is more frequent in the setting of right isomerism than in usual arrangement.¹⁷

The other universally constant feature of the venoatrial connections in the presence of isomeric right atrial appendages is absence of the coronary sinus, this channel being a component of the morphologically left atrioventricular junction. When the pectinate muscles extend bilaterally to the crux, there is no room to enclose the sinus within the junctions (see Fig. 22-4). It may be anticipated, nonetheless, that some patients with absence of the spleen may possess a coronary sinus, since not all patients with asplenia have isomeric right atrial appendages.

If totally anomalous pulmonary venous connection, together with absence of the coronary sinus, are the distinguishing atrial features of hearts with isomeric right atrial appendages, then it is an anomalous connection of the inferior caval vein which draws attention to the potential presence of isomeric left atrial appendages. Most frequently, the suprarenal segment of the inferior caval vein is totally absent. The abdominal segment of the caval vein continues through the azygos venous system to drain to either the right- or the left-sided superior caval vein (Fig. 22-10). In patients with left isomerism, both accessory venous systems are strictly hemiazygos, since the hemiazygos vein is a morphologically left structure. It is

simpler, nonetheless, to describe communication via the azygos venous system, and then to account for the right- or left-sided location of the anomalous venous channel. Although right-sided azygos continuation has been noted in the setting of right isomerism, albeit rarely,¹⁸ continuation through the left-sided azygos veins has been reported only in association with left isomerism, or very rarely, in patients with usual atrial arrangement or mirror-imaged arrangement. In terms of connection of the hepatic veins, a confluent suprahepatic channel was present in one-third of cases with isomeric left atrial appendages in the case material of the Children's Hospital of Pittsburgh (see Fig. 22-10). The presence of separate connection of the hepatic veins, when combined with the relationship of the abdominal great vessels relative to the spine, had been considered a reliable means of distinguishing non-invasively the presence of right and left isomerism.¹⁹ We now know this not to be strictly accurate. It is difficult, if not impossible, to distinguish with certainty cases as having isomerism simply by studying the relationships of the abdominal great vessels to the spine. This is not to detract from the immense value of this feature when used as the initial step in the ultrasonographic assessment of sequential segmental anatomy.¹⁹ When note is taken of the overall connections of the pulmonary veins, the inferior caval vein, and the drainage of the hepatic veins to the atriums, along with the arrangement of the coronary sinus, it should always be possible to distinguish between the right and left forms of isomerism. This is certainly not the case with the connections of the superior caval veins. Bilateral connections to the roofs of the right- and left-sided atriums are frequent in either setting. In those with isomeric left appendages, these connections are anomalous on each side. In those with isomeric right atrial appendages, in contrast, they are anatomically normal, with each caval vein appropriately related to a terminal crest, and with sinus nodes present subepicardially in the bilateral terminal grooves (Fig. 22-11).

The drainage of the veins from the heart itself is also abnormal in both right and left isomerism. This is no more than to be expected in right isomerism since, in the universal absence of the coronary sinus, there is no transverse channel within the atrioventricular groove to collect the venous return from the heart. The variability in termination of the individual cardiac veins is surprising. The veins can terminate directly, take a crooked course for a short distance along the atrioventricular groove, or traverse the atrial wall for some distance before draining into the atrium well away from the atrioventricular groove, often adjacent to the opening of a pulmonary or systemic vein (Fig. 22-12). Such direct, crooked, or distant venous terminations are also to be found in hearts with isomeric left appendages, but a coronary sinus receiving all the coronary venous return is more frequent in cases with left isomerism.²⁰

Atrial Septum

The degree of atrial septal deficiency also fails positively to discriminate between patients having isomeric right or left atrial appendages. In those with right atrial appendages bilaterally, most frequently there is simply a strand of atrial tissue which spans a common atrial cavity (see Fig. 22-4). It is rare to find the atrial septum completely lacking, but in

Figure 22-10 The heart and lungs from this patient with left isomerism are photographed from behind. The venous return from the abdomen, apart from that from the liver, reaches the heart through the azygos vein, which runs together with the right-sided aorta.

Figure 22-11 The pictures show the internal aspect of the right-sided (Panel A) and left-sided (Panel B) atrial chambers from a patient with isomeric right atrial appendages. The presence of terminal crests bilaterally is obvious.

Figure 22-12 The cartoon shows the inferior surface of a heart with isomeric atrial appendages, illustrating the concept of direct, crooked, and distant return of coronary venous drainage when the coronary sinus is absent.

most cases there is, effectively, a common atrium. In about a quarter of cases, the septum is well-formed superiorly in association with an atrioventricular septal defect, while very rarely the septum can be intact, or else the oval foramen be probe patent. An effectively common atrium is to be expected in about one-half of cases with left isomerism (see Fig. 22-5). An atrioventricular septal defect is also present in nearly half, while the septum can be virtually intact in nearly one-fifth.

Atrioventricular Junctions

As with hearts in which the atrial appendages are lateralised, chambers with isomeric appendages can each be connected to their own ventricles, or else the atria can be connected to only one ventricle. When the atrioventricular connections are biventricular, it is essential also to describe the ventricular topology. This is because there are two patterns to be found, irrespective of whether the isomeric appendages are of right or left morphology. In the first pattern, the right-sided atrium, be it associated with a morphologically right or left appendage, will be connected to the morphologically right ventricle (Fig. 22-13A), and the left-sided atrium to the morphologically left ventricle. This ventricular topology is right-handed. In the second arrangement, the right-sided atrial chamber, which again may possess either a morphologically right or left atrial appendage, will be connected to a morphologically left ventricle, and the left-sided atrium will be connected to a morphologically right ventricle. In this second pattern, the ventricular topology is left-handed (see Fig. 22-13B). When we initially defined such atrioventricular connections, we described them as ambiguous. We now recognise that it is better to describe them as biventricular and mixed (see Fig. 22-13), proceeding always to describe the ventricular topology present and, if necessary, any abnormal and unexpected ventricular relationships. Biventricular and mixed atrioventricular connections are much more frequent in the setting of isomeric left atrial appendages, and most of these patients should be anticipated to have right hand pattern ventricular topology.

Univentricular atrioventricular connections, typically with double inlet via a common atrioventricular valve, are significantly more frequent in hearts with right rather than left isomerism. In about one-third of such instances, the univentricular connection will be to a morphologically right ventricle, usually left-sided, but in some it will not be possible

Figure 22-13 The cartoon shows the concept of biventricular and mixed atrioventricular connections. The connections would still be mixed if the appendages were of left morphology bilaterally, rather than the isomeric right variant shown.

to find a second ventricle. The majority of hearts will have double inlet to a dominant morphologically left ventricle, but solitary and indeterminate ventricles are more frequent with isomerism than in any other setting. Absence of the left-sided or right-sided atrioventricular connection is rare, but can be found with any ventricular morphology. Thus, when the atrial appendages are isomeric, any type of univentricular atrioventricular connection must be anticipated, along with any possible ventricular morphology. Fewer hearts with left isomerism have univentricular atrioventricular connections, but the same variability must be expected.

Irrespective of the presence of biventricular or univentricular atrioventricular connections, most hearts with right isomerism have a common atrioventricular junction guarded by a common valve (see Fig. 22-4). In autopsy series, the finding of normally located and unobstructed mitral and tricuspid valves is rare. In hearts with double inlet, a common valve is to be expected irrespective of the morphology of the dominant ventricle.

As would be expected, with such a high incidence of atrioventricular septal defects, the ventricular septum in the majority of hearts with biventricular atrioventricular connections is deformed in the anticipated fashion. In the very rare cases with right isomerism but without an atrioventricular septal defect, ventricular septal defects are the rule, and typically are perimembranous or muscular. In those with left isomerism, however, the ventricular septum is more frequently intact, including those having an atrioventricular septal defect with shunting exclusively at atrial level. In all hearts with univentricular atrioventricular connection, be there right or left isomerism, those with incomplete ventricles have interventricular communications as anticipated for the ventricular morphology present (see Chapter 31).

Ventriculo-arterial Junctions

Amongst the entire group of hearts with isomeric atrial appendages, there is just as much variability in type and mode of ventriculo-arterial connection, infundibular morphology, and arterial relationships as encountered in congenital cardiac disease as a whole.²¹ Certain patterns occur with significantly different frequencies in hearts with

isomeric right as opposed to left appendages. Pulmonary obstruction or atresia is significantly more common in association with right than with left isomerism. When there is pulmonary atresia, almost always the pulmonary supply is duct-dependent, although supply through systemic-to-pulmonary collateral arteries can sometimes be found. Obstruction of the left ventricular outflow tract, with aortic coarctation or atresia, is much commoner with left isomerism. Analysis of the ventriculo-arterial junctions as a whole shows significant differences between the two isomeric arrangements. An anterior right-sided aorta, along with subaortic or bilateral infundibulums, is commoner with right isomerism, while concordant ventriculo-arterial connections are more frequent in left isomerism.

Conduction Tissues

The morphology of the sinus node reflects the arrangement of the atrial appendages. In right isomerism, there are bilateral sinus nodes, each related to the terminal crest and the cavoatrial junction in normal fashion.^{10,22} In left isomerism, in contrast, there are no terminal crests, and no right atrial appendages. The sinus node, therefore, cannot occupy its normal position. Indeed, in most hearts studied, it has not proved possible to identify with certainty the sinus node.²² When a candidate for the sinus node is discovered, it tends to be grossly hypoplastic and located in the atrial wall adjacent to the atrioventricular junctions.

The disposition of the atrioventricular conduction axis reflects both the atrioventricular connection present and the ventricular topology.²² When there are biventricular atrioventricular connections, the dominant feature is the ventricular topology. An atrioventricular node in its regular position, with a postero-inferior penetrating atrioventricular bundle, is found with right hand topology, the axis of conduction tissue being deviated posteriorly in presence of an atrioventricular septal defect. When there is left hand pattern ventricular topology, there is either an anterior atrioventricular node and the conduction system is found as is typical for congenitally corrected transposition, or else a sling of conduction tissue is present running along the crest of the ventricular septum, producing a connection with two atrioventricular nodes. With univentricular atrioventricular connection, ventricular morphology becomes the dominant feature. When the left ventricle is dominant, the atrioventricular node is found in anterior position, with the bundle varying its relationship to the outflow tract of the left ventricle according to the position of the incomplete right ventricle (see Chapter 31). With connection to a dominant right ventricle, the conduction system is normally situated when the incomplete left ventricle is left-sided, but an anterior node or sling may be found when the incomplete left ventricle is right-sided. The atrioventricular conduction tissues are bizarre when there is a solitary and indeterminate ventricle.²²

Cardiac Position

An unusual position of the heart should always alert to the presence of isomerism. As reported in one extensive autopsy series⁵, the heart was left-sided in three-fifths, right-sided in three-tenths, with one-tenth showing a midline arrangement. The location of the heart, and the position of its

apex, however, failed to discriminate between right and left isomerism.

Arrangement of the Thoraco-abdominal Organs

Jumbled-up arrangement of the abdominal organs, or visceral heterotaxy, has long been recognised as the hallmark of the splenic syndromes. For some time, a midline liver was also considered a marker, but more recent experience shows this often not to be the case, the abdominal organs not typically being arranged in symmetrical fashion. Our own experience⁵ confirms that thoracic isomerism cannot reliably be diagnosed on the basis of the disposition of the abdominal organs, particularly with regard to the morphology of the spleen. Should splenic tissue be absent, this should be documented, since this feature carries connotations for the immune state of the patient. The spleen, nonetheless, whilst expected to be absent in those with right isomerism, can also be absent in those with isomeric left atrial appendages. The arrangement of the remaining abdominal organs is also of significance. A short mesentery can lead to intestinal volvulus, and occurs in right or left isomerism.⁸ The pancreas tends to be short or annular only in the presence of left isomerism.

The morphology of the thoracic organs, specifically the bronchial tree, is a much better guide to the presence of isomerism of the atrial appendages. Bilateral long and hyparterial bronchuses are indicative of left isomerism, and bilateral short and eparterial bronchuses of right isomerism, respectively. Not all cases with isomeric atrial appendages have bronchial isomerism. Thus, while examination of the penetrated chest radiograph was considered a useful step in the evaluation of the infant or child suspected of having isomeric atrial appendages, it is now rarely used as a diagnostic tool.

Visceral Symmetry without Isomeric Atrial Appendages

Whilst the focus of this chapter is on isomerism of the atrial appendages, there is increasing evidence to suggest that varying degrees of visceral symmetry may occur in the presence of usual atrial arrangement. Indeed, a symmetrical arrangement of some of the organs appears to occur with significantly greater frequency than does isomerism of the atrial appendages. Abnormal arrangement of the abdominal organs, and pulmonary isomerism, appear to be the most common abnormalities. In our reviews of the autopsy data from Children's Hospital of Pittsburgh, we noted a number of instances in which a tendency to visceral symmetry occurred with usual atrial arrangement.^{16,23} In a genetic analysis of isomerism, a healthy sibling of a proband with right isomerism was noted to have left bronchial isomerism.²⁴ Abnormal lateralisation, with a tendency to visceral symmetry, can be found, therefore, in patients with structurally normal hearts. These observations have important implications for research into the aetiology of abnormal lateralisation, and for genetic counselling.²⁵ For the purposes of genetic studies, cases showing any degree of abnormal lateralisation should be distinguished from the normal. External phenotype, and cardiac morphology, is an inadequate indicator of the overall arrangement of the organs. Thus, each system of organs requires individual and specific analysis. It is best to avoid inferring the morphology of one group of organs

based on observations in another. At the same time, for these purposes above all, it is necessary to stratify visceral heterotaxy into the subsets of right and left isomerism.

EXTRACARDIAC ANOMALIES

Malformations of the bodily organs, in addition to splenic anomalies and abnormal arrangements, occur with significant frequency in patients with isomeric atrial appendages.^{8,9,26–28} The malformations, present in at least one-fifth of cases, included lesions involving the central nervous system, skeletal anomalies, and genitourinary anomalies. Gastrointestinal abnormalities can produce intestinal obstruction, either because of an annular pancreas or fibrous bands,²⁷ or subsequent to volvulus.⁸ Abnormal dilated pulmonary and pleural lymphatics have been described in patients with asplenia syndrome, with the reported changes considered unrelated to any obstruction to pulmonary venous return.²⁹

A wide range of anomalies is also observed in those having left isomerism. The most specific association between left isomerism, or polysplenia, and anomalies of other organ systems is biliary atresia, with or without hypoplasia or agenesis of the gallbladder. While this finding is seen in some patients with isomeric left atrial appendages, the combination of biliary atresia and multiple spleens often occurs in the setting of a structurally normal heart.^{15,16} The fact that many of these patients have usual atrial arrangement does not imply the normal development of left-right asymmetry, since left bronchial and left pulmonary isomerism, intestinal malrotation, and interruption of the suprarenal portion of the inferior caval vein are frequently observed when polysplenia accompanies biliary atresia.¹⁶ Although extracardiac anomalies are common in patients with isomeric atrial appendages, recognisable patterns of malformations that would lead to the designation of a specific syndrome or malformation sequence are rare.²⁷

ISOMERISM AND CONJOINED TWINNING

There is a fascinating association between conjoined twins and disruption of normal left-right asymmetry. Complex cardiac malformations, and absence of the spleen in one of the twins, have been well described.^{27,30–32} The most complex cardiac anomalies are usually, but not always, observed in the right hand twin. Features of left isomerism, in contrast, are rarely observed.

MORPHOGENESIS

Most early studies of the development of the splenic syndromes concentrated their attention upon the spleen.^{3,9} While of undoubted value in terms of knowledge of splenic development, this approach does little to clarify the grossly abnormal cardiac development associated with isomerism. Here, as with the analysis of the heart itself, the significant feature is the isomeric nature of the atrial appendages. The significant point from the stance of development is that the apical parts of the ventricles, which confer morphological rightness or leftness, balloon in series from the inlet and outlet parts of the ventricular component of the primary heart tube, while the atrial appendages balloon in parallel from the atrial component (see Chapter 3). It is not surprising, therefore, that the isomeric malformation should

produce duplication of the atrial appendages, without producing symmetry of the ventricles. The venous malformations are then equally well explained. With bilateral morphologically right atrial appendages, there will be no focus for incorporation of the pulmonary venous component. In normal development, this occurs by lumenisation of the pulmonary vein in the developing mediastinum, the vein using the dorsal mesocardial connection between the heart tube and the body as its entrance to the heart (see Chapter 3). These connections are grossly abnormal when both appendages develop with right morphology. The intrapulmonary venous plexuses developing in the mediastinum will, therefore, join up with suitable systemic channels to form totally anomalous connections, or else will connect directly but anomalously to the roof of the atrial chambers. Persistence of the initial bilateral symmetry of the systemic venous tributaries accounts for the usual finding of bilateral superior caval veins and absence of the coronary sinus. The bilateral formation of the terminal crests accounts for the development of bilateral sinus nodes. Since the inferior caval vein is able to drain in normal fashion to the atrial chamber, the hepatic veins will also develop normally.

When both the atrial appendages develop morphologically left characteristics, the pulmonary venous channels can be incorporated into either side of the atrium, accounting for the common finding of bilateral pulmonary venous connections. Because the terminal crest develops from the morphologically right side, the superior caval venous channels will never drain in normal fashion in hearts with left isomerism, and there will be no potential for formation of a normal sinus node. Since the ventricles develop in series, they can form in any fashion as occurs in malformations without isomerism. This is reflected in the variation seen in ventricular morphology. It is not clear why isomerism of the right appendages should more frequently be associated with a univentricular atrioventricular connection, nor with either pulmonary atresia or stenosis.

Much has now been learned concerning the genetic pathways producing these changes, with experiments confirming the reality of isomerism of the atrial appendages. Thus, it is known that cilia in the primitive node create a wave that drives molecules in one specific direction across the cells of the developing embryo, with expression of the gene *Nodal* mostly confined to the left side.³³ The wave of molecular material produced from the node that influences development of lateralised features is stopped from crossing the midline of the embryo, this process known to be under the influence of the gene *Sonic hedgehog*.³⁴ Because of this midline barrier, other genes, such as *Lefty*, and *Pitx2*, along with the gene *Cited2*, also known to be part of the genetic cascade,¹⁴ have their expression confined to the left side of the body, thus producing the morphologically left characteristics (Fig. 22-14). Knocking out genes such as *Pitx2* or *Cited2* in mice then produces animals with unequivocal right isomerism (Fig. 22-15),^{14,35} while knocking out *Sonic hedgehog* permits the left-forming genes to occupy the right side of the body, and produces left isomerism^{34,36} (Fig. 22-16).

INCIDENCE

It is difficult to calculate precisely the incidence of isomerism. This is because, until recently, the malformation has been described under a bewildering plethora of titles,

Figure 22-14 The cartoon shows the basic plan of the developing embryo at the stage of a flat disc (see Chapter 3). It shows how genes such as *Lefty* and *Pitx2* are confined to the left side (L) by virtue of a midline barrier involving the genes *Lefty-1* and *Sonic hedgehog*.

Figure 22-15 The scanning electron micrograph shows the atrial chambers of *Pitx2* knock-out mouse from the ventricular aspect. The isomeric nature of the morphologically right appendages and venous valves is unmistakable. (Courtesy of Professor Nigel Brown, St George's University, London, United Kingdom.)

and has been recognised most frequently at postmortem rather than during life. In the New England survey,³⁷ 95 of the 2251 infants presenting with congenital heart disease had visceral heterotaxy. Another study³⁸ estimated the incidence at around 1 in 40,000 live births. In a population-based study of all infants born with congenital asplenia in British Columbia, we calculated an incidence for right isomerism of 1 in 22,000 live births.¹⁷ The Baltimore–Washington Infant Study³⁹ identified heterotaxy as representing 2.3% of congenital cardiac disease seen in infants, giving an incidence of 1 in 9158 live births. In the Active Malformation Surveillance Program at the Brigham and Women's Hospital, Boston,⁴⁰ prevalence of heterotaxy among the offspring of mothers who had planned delivery at that hospital was approximately 1 per 10,000 total births. The degree of potential underestimation of incidence and prevalence given by these studies is difficult to

Figure 22-16 This histological section, in the frontal plane, is from a *Sonic hedgehog* knock-out mouse. Both the atrial appendages are of left morphology, with a symmetrical midline systemic venous sinus. (Courtesy of Dr Victoria Hildreth and Professor Deborah Henderson, University of Newcastle, Newcastle-upon-Tyne, United Kingdom.)

establish. It seems likely that most cases of right isomerism are recognised in infancy because of the presence of severe forms of cyanotic heart disease. Failure to recognise left isomerism is more likely because of the wider range of associated heart disease, including mild forms that may not even warrant surgical intervention. We have observed patients with isomerism of the left atrial appendages with interruption of the inferior caval vein and no other cardiac anomalies. Such patients are unlikely to be identified in life unless extracardiac anomalies, such as biliary atresia, lead to cardiac evaluation. It may be that patients with isomeric atrial appendages represent only the tip of the iceberg of the total population with abnormal lateralisation.

AETIOLOGY

There is compelling evidence that there is no single aetiology responsible for the development of abnormal lateralisation and isomerism. Evidence for causal heterogeneity comes from studies of humans and from animal models. Chromosomal anomalies are only rarely associated with visceral heterotaxy. We found no karyotypic abnormalities among infants with right isomerism and asplenia.¹⁷ In the Baltimore–Washington Infant Study, 1 of 99 infants with heterotaxia had trisomy 13, and two other infants had unspecified chromosomal abnormalities.³⁹ An association between trisomy 13 and abnormalities of left-right development, nonetheless, has been noted,⁴¹ as had a case of balanced translocation of chromosomes 12 and 13 associated with right isomerism and asplenia.⁴² This latter observation suggests that a gene at break points 12q13.1 or 13p13 might be important in development of normal asymmetry. A patient with heterotaxy was also noted to

have a new, apparently balanced, reciprocal translocation with breakpoints at 6q21 and 20p13.⁴³ Because another patient with heterotaxy was previously reported with such a new balanced translocation involving chromosome band 6q21, the authors speculated that a critical gene, or genes, in this region may be important in the development of heterotaxy. Several studies of families also suggest that hereditary single gene defects may be important aetiological factors.^{44–46} Probable autosomal dominant inheritance has been described in more than one family.^{47,48} Another family with heterotaxy provides clear evidence of X-linked recessive inheritance.⁴⁹ Linkage analysis in a second family with this mode of inheritance mapped the abnormal gene or genes to the region Xq24–q27.1.⁵⁰ More recently, mutations in the zinc finger transcription factor *ZIC3* have been demonstrated to cause at least some cases of X-linked heterotaxy.⁵¹ Molecular cytogenetic investigations in another patient identified a breakpoint spanning a small region on the X chromosome containing the *ZIC3* gene.⁵² Although distinct anatomical differences of the heart and other organs distinguish patients with left and right isomerism, it is interesting to note that patients have been identified with both right and left isomerism, along with multiple or absent spleens, in several familial cases of visceral heterotaxy.^{47,53,54} Anatomical variations, therefore, do not necessarily reflect genetic differences.

At present, we do not know the proportion of cases of human isomerism caused by inheritable single gene defects. The finding of three pairs of siblings in 60 cases of asplenia or polysplenia gives a recurrence risk of just under 5%,³⁸ which is much too low for simple autosomal recessive transmission, yet much higher than would be predicted from the multi-factorial threshold model. We found no familial cases among 43 examples of congenital asplenia.¹⁷ Others calculated a risk of recurrence of 3% to 4%.²⁴ Despite this, the Ivemark syndrome is listed as an autosomal recessive condition.^{55,56} The lower than expected risk of recurrence is explained in various ways, including causal heterogeneity, low fertility of affected patients, reduced penetrance of some recessive traits, and fetal loss. We observed only one case of right isomerism, nonetheless, amongst 5000 post-mortems performed on early fetuses and stillbirths over a 21-year period in British Columbia.¹⁷

While the study of family kindreds may supply important information about modes of human inheritance, animal models, including knock-out and knock-in models, are a more potent tool for studying the molecular pathways that lead to abnormal lateralisation. Fortunately, several animal models of visceral heterotaxy exist, and have been studied in detail. The *iv/iv* mouse has been studied most comprehensively.⁵⁷ This recessive trait was initially considered to be a model of mirror imagery, in which homozygous animals exhibit random lateralisation, with half manifesting mirror-imaged arrangement.⁵⁸ Subsequent, more detailed anatomical studies showed that a minority of the affected animals had visceral heterotaxy, with isomerism of the atrial appendages, along with both splenic abnormalities and complex cardiac defects strongly reminiscent of human hearts with isomerism.⁵⁹ Other mutations in the mouse, the result of insertion of transgenes, have resulted in abnormalities of lateralisation. Individual *inv/inv* mice show evidence of isomerism as well as mirror imagery,⁶⁰ and the insertional mutation has been

mapped to mouse chromosome 4. The *legless* mice represent another insertional mutation associated with partial deletion of chromosome 12. The genetic defect appears to involve the *iv/iv* locus. Molecular genetic studies of these models have helped bridge the gap between genetics and our understanding of the molecular pathways involved in normal and abnormal lateralisation, as discussed earlier. Abnormalities in nodal cilia and nodal flow are a common theme in several animal models of abnormal lateralisation with visceral heterotaxy, including the *iv/iv* and *inv/inv* models. For more detailed understanding of the molecular pathways involved in abnormal lateralisation, the reader is referred to several excellent reviews.^{8,61,62} When the genes involved in lateralisation abnormalities have been fully localised within the mouse genome, analysis of syntenic regions on human chromosomes and studies of affected human kindreds should result in characterisation of the genes involved in human syndromes associated with isomerism and abnormal lateralisation.⁶³

Other animal studies suggest that non-genetic factors may result in abnormal lateralisation. In the non-obese diabetic mouse, visceral heterotaxy and isomerism of the atrial appendages are frequently seen when diabetes develops early in pregnancy.⁶⁴ Retinoic acid has also been reported to cause heterotaxy in rat embryos,⁶⁵ and isomerism has been produced in offspring of pregnant rats kept at warm temperatures.⁶⁶ At the present time, no specific environmental factors have been implicated in the aetiology of human heterotaxy.

CLINICAL FINDINGS

Increasingly, the diagnosis of isomeric atrial appendages, and abnormal arrangements of the thoraco-abdominal organs, is being made in fetal life.⁶⁷⁻⁷³ This largely reflects the more frequent use of ultrasound in the second trimester, including four-chamber cardiac screening in many centres. Even when cardiac abnormalities are not detected, the presence of abnormal arrangement of the abdominal organs frequently leads to referral for fetal echocardiography. In addition, a proportion of fetuses with left isomerism present with bradycardia, with or without non-immune hydrops.^{69,74} This finding also results in referral for fetal echocardiography, which should, in turn, lead to an accurate anatomical diagnosis.^{67,72} The most challenging aspect of fetal diagnosis is accurate delineation of systemic and pulmonary venous connections. The latter is of greatest clinical importance in the neonatal period, since obstruction to pulmonary venous return is common in right isomerism, and is a major predictor of post-natal survival. In general, the intracardiac structures and connections are accurately defined in experienced hands. There is a tendency for right isomerism predominantly to affect males,^{17,38} but with conflicting findings for left isomerism.^{38,75} Gender, therefore, cannot be used reliably to predict cardiac or splenic state in infants with suspected isomerism. Almost without exception, infants with right isomerism have obstruction of the pulmonary outflow tract, as well as common mixing, and pulmonary atresia is present in two-fifths.⁷⁶ When the pulmonary valve is patent, obstruction is generally at least moderate in nature, and presentation on the first or second day of life is usual.¹⁷ While cyanosis is by far the most common presentation,

occasional infants with right isomerism present with severe respiratory distress and cyanosis resulting from obstructed anomalous pulmonary venous connection. Several reports have drawn attention to the potential for masking of the obstructed pulmonary venous return by reduction in the flow of blood to the lungs concomitant with closure of the arterial duct. In this situation, the obstruction may be unmasked by administration of prostaglandin E₁, or by the placement of a systemic-to-pulmonary shunt, resulting in the development of pulmonary oedema.⁷⁷⁻⁸⁰ It seems likely that there has been a bias in the literature towards reports that emphasise this clinical dilemma. This probably reflects the wish to provide a cautionary tale to other clinicians by those groups who have experienced this serious clinical problem. In our experience, most obstruction to pulmonary venous return is apparent in the neonatal period, when there is early development of pulmonary oedema and severe cyanosis.⁸¹ On occasion, nonetheless, pulmonary venous obstruction may be mild at birth, and may progress over the first few weeks and months of life. This is most common when the anomalous venous connection is supracardiac in nature. Patients with right isomerism may occasionally present with serious extracardiac anomalies²⁶⁻²⁸ or, more rarely, with a murmur originating from the pulmonary outflow tract when pulmonary stenosis is mild and cyanosis has gone unrecognised. In these situations, physical examination may provide clues to the presence of abnormal arrangement of organs, such as a right-sided cardiac apex or a midline liver.

The clinical findings in left isomerism are non-specific and will reflect the associated lesions. In contrast to right isomerism, the heart disease may be relatively mild. Indeed, we have observed the presence of isomerism of the left atrial appendages in association with interrupted inferior caval vein and no other cardiac or vascular abnormalities. Such patients may never be diagnosed as having isomerism unless extracardiac anomalies, such as biliary atresia or intestinal malrotation, draw attention to the abnormal arrangement of the abdominal organs. In a recent review of all patients diagnosed with isomeric left atrial appendages at the Children's Hospital of Pittsburgh, we noted that two-thirds had simpler forms of cardiac disease potentially suitable for biventricular repair. The remaining patients had complex cyanotic heart disease, frequently associated with univentricular atrioventricular connection. Although some infants with left isomerism present with cyanosis because of the combination of common mixing and obstruction of the pulmonary outflow tract, as for right isomerism, many infants with complex disease and isomeric left appendages present with cardiac failure owing to left-to-right shunting without pulmonary obstruction, and frequently with obstruction of the left ventricular outflow tract. Indeed, some will present with shock and congestive failure because of hypoplasia of the left heart, with or without signs of coarctation. These infants are frequently referred to tertiary centres with a suspected diagnosis of hypoplastic left heart syndrome. Cardiac failure may also be evident at presentation when severe regurgitation of a common atrioventricular valve, or severe bradyarrhythmia, is present at birth. The two often co-exist, and they frequently lead to fetal hydrops and intra-uterine death.^{68,74,82} When such infants survive to term, they are frequently moribund at presentation and the prognosis is grave. Progression of

atrioventricular block in fetal life has also been observed in patients with left isomerism.⁶⁹

INVESTIGATIONS

The Electrocardiogram and Abnormalities of Cardiac Rhythm

The electrocardiographic findings are not specific for a diagnosis of isomerism, but once isomerism is identified, the pattern present should help differentiate most into either right or left isomerism. In right isomerism, the frontal plane P wave axis is usually inferior^{83–85} but may be to the left, as with the usually arranged atrium, or to the right, as with the mirror-imaged atrium. In some instances, right- and left-sided atrial origin of the P wave is present at different times in the same patient (Fig. 22-17),^{83–85} reflecting activity of bilateral sinus nodes.⁸⁶ Slow atrial rhythms, with or

without junctional escape, are very rare in right isomerism. In left isomerism, true sinus rhythm is less common, as might be anticipated from the known hypoplasia of the sinus node in patients with isomeric left appendages.^{86,87} About four-fifths of patients with left isomerism have a superiorly oriented axis for the P wave. This usually results from an ectopic atrial focus but is sometimes caused by junctional escape rhythm. In some patients, it is possible to find progression between these patterns (Fig. 22-18). Atrial rates below the second percentile for age have been noted in half of patients with left isomerism, being persistent in one-tenth. In many patients, progressive slowing was noted with advancing age. Despite these observations, the atrial or nodal rhythms were usually of adequate rate to prevent symptoms in childhood. Progressive slowing has been seen in adulthood, leading to the need for placement of a permanent pacemaker.⁸⁸ Atrioventricular block is

Figure 22-17 Electrocardiographic limb lead recordings taken a few weeks apart from a 12-year-old child with right isomerism. **A**, The P wave axis is normal, consistent with activation from a right-sided sinus node. **B**, Change of the axis consistent with activation from a left-sided sinus node.

Figure 22-18 Electrocardiographic tracings from the limb leads of a child with left isomerism reveal changing patterns with age. **A**, In infancy, a low atrial rhythm with a superiorly orientated axis of the P wave is seen. **B**, Later in childhood, there was evidence of another ectopic atrial rhythm. **C**, Two years later, the patient developed permanent junctional rhythm.

Figure 22-19 These electrocardiographic limb leads from a newborn show a superior P wave axis together with complete heart block. The combination is highly suggestive of left isomerism, which was indeed present. Note also the features of marked atrial enlargement.

exceedingly rare in right isomerism, but at least one case has been reported.⁸⁹ By contrast, varying degrees of atrioventricular block are common in left isomerism (Fig. 22-19). These findings reflect differences in the anatomy of the conduction system, as discussed earlier in this chapter. For those diagnosed in fetal life, there appears to be a higher incidence of heart block⁶⁸ than seen in those diagnosed postnatally.^{84,85} Overall, complete atrioventricular block is observed in one-tenth of cases of left isomerism.^{84,85} The morphology and axis of the QRS complex in hearts with isomeric appendages will reflect the ventricular morphology and the cardiac position. In view of the strong association with atrioventricular septal defect, it is not surprising that a high proportion of cases have a superiorly oriented frontal QRS axis. As is the case with the P wave, it is also the case that different QRS axes can exist in the same patient. This reflects the presence of dual atrioventricular nodes joining a ventricular sling of conduction tissue.²² These abnormally structured atrioventricular nodes and bundles allow retrograde conduction, which can be identified by ventricular pacing. When such dual conduction pathways are present, they frequently form atrioventricular re-entry circuits. Such re-entry is an important mechanism of tachycardia, particularly in those with right isomerism. Because of the variation in QRS morphology, this situation can easily be misinterpreted as representing ventricular tachycardia. Indeed, in our experience such atrioventricular re-entrant tachycardia is much commoner than atrial tachycardia in the setting of right isomerism. Atrial tachycardia, nonetheless, can be caused by competition between the two sinus nodes. Atrial fibrillation, in contrast, is rare in infants with right isomerism.

Chest Radiography

Evaluation of the chest radiograph can provide strong evidence for the presence of isomerism. In the neonatal period, abdominal structures are frequently included on the plain chest radiograph. Abnormal position of the stomach bubble, and a large midline liver, may provide immediate

clues to the presence of visceral heterotaxy. Cardiac malposition is also often present. If umbilical venous and arterial catheters have been placed, the characteristic relationships of the aorta to the inferior systemic venous drainage will be apparent. More specifically, the presence of isomerism of the atrial appendages can be inferred, with some exceptions, from the finding of bronchial isomerism. As long ago as 1970, it was suggested that isomerism of the bronchial tree could be used as a means of diagnosing these syndromes during life.⁹⁰ Although it is sometimes possible to be confident about the diagnosis of bronchial isomerism from the plain chest radiograph, this has not proved to be consistently reliable.⁹¹ A technique using high kilovoltages and filters provides superior images of the bronchial anatomy when compared to standard chest radiograph.²² On the radiograph, which is exposed with rather less irradiation than a standard chest film, bone detail is effaced to a considerable degree so that the interfaces of soft tissue and gas in the mediastinum and adjacent lung are readily seen. Exposure time is very short, and breathing blur, therefore, is rarely a problem. Using this technique, adequate bronchial visualisation can be obtained in almost all infants. The position of the aortic arch, assessed from the side of tracheal indentation, is also usually apparent. These views are now rarely performed, since it has been demonstrated that cross sectional echocardiography can provide similar information about atrial arrangement, but without the need to assume bronchio-atrial concordance.

Other important information can be gleaned from the plain chest radiograph of infants with suspected isomerism. Absence of the shadow produced by the inferior caval vein on the lateral chest radiograph may suggest azygos continuation of an interrupted inferior caval vein.⁹² Particular attention should also be paid to the pulmonary vasculature. This is of great importance in patients with right isomerism, where almost all infants will have pulmonary arterial obstruction and totally anomalous pulmonary venous connection. Increased vascularity in this setting should lead to the immediate suspicion of obstruction to pulmonary venous return (Fig. 22-20A). When severe cyanosis is present, even normal to mildly increased vascularity should raise this suspicion, since pulmonary oligoemia would be anticipated if pulmonary venous return were unobstructed (see Fig. 22-20C and D). With careful clinical evaluation, review of the chest radiograph, and cross sectional echocardiographic interrogation, the diagnosis should be sufficiently secure to prevent the unmasking of pulmonary venous obstruction by inappropriate placement of a systemic-to-pulmonary shunt without concomitant relief of pulmonary venous obstruction.⁸¹ When marked discrepancies in vascularity exist between different lung segments, mixed anomalous pulmonary venous connection with varying degrees of obstruction should be suspected (see Fig. 22-20B).

Echocardiography

Cross sectional echocardiography, based on the principles of sequential segmental analysis (see Chapter 18A) can provide a complete anatomical diagnosis in almost all cases of isomerism. Some time ago,¹⁹ it was suggested that atrial arrangement could be identified by demonstrating the characteristic relationships of the aorta to the inferior systemic

Figure 22-20 These radiographs show the spectrum of pulmonary venous obstruction seen in four newborns with right isomerism. Note also the right-sided location of the heart in three of the panels. A, In this child, there is severe pulmonary oedema. This can be confused with the radiographic features of parenchymal pulmonary disease, such as aspiration of meconium. B, In the child with a left-sided heart, the greater severity of pulmonary oedema on the right is explained by the presence of mixed totally anomalous pulmonary venous connection, with more severe obstruction of the right-sided pulmonary venous return. C, The increase in pulmonary vascularity is subtle but, in the presence of severe cyanosis, the absence of pulmonary oligoemia raises the suspicion of obstructed pulmonary venous return. D, This child has mild obstruction from totally anomalous pulmonary venous connection to a left superior caval vein.

venous drainage in short-axis sections of the abdomen taken just below the xiphisternum. This technique retains its value, but in addition, careful interrogation is required of the hepatic venous return. In the person with usual lateralised bodily arrangement, the inferior caval vein is identified to the right of the spine, with the aorta usually lying anterior and just to the left of the vertebral column (Fig. 22-21A). The venoatrial connections can then readily be demonstrated by rotating the transducer into the long axis and tracing the venous channel caudally, at the same time observing its connections with the hepatic veins. With usual atrial arrangement, the hepatic veins can be seen to join the inferior caval vein just proximal to its connection with the right atrium. The arrangement is mirror-imaged when the atrial appendages themselves show mirror-imagery (see Fig. 22-21B). In right isomerism, the aorta and the inferior caval vein are usually juxtaposed to the left or right of the spine, with the inferior caval vein found in anterolateral position (see Fig. 22-21C). The inferior caval vein receives all of the hepatic veins in the majority of patients.⁶ In about one-fifth, bilateral hepatic venous drainage can be demonstrated. In patients with left isomerism, there is interruption of the inferior caval vein in approximately seven-tenths of cases. The abdominal venous return reaches the heart through the azygos or hemiazygos vein, which runs on the same side of the spine as the aorta but in a posterior position. This is easily demonstrated during short-axis scanning of the upper abdomen (see Fig. 22-21D). Hepatic venous return is markedly variable in the setting of left isomerism. The majority demonstrate a confluence to an atrium, but bilateral drainage of the hepatic veins to each atrium is also common.⁶ Careful echocardiographic evaluation of the hepatic venous drainage is mandatory, therefore, in all patients suspected of having isomerism to

aid in surgical planning for separation of the circulations. The precise connections cannot be inferred. Recognition of bilateral drainage will also aid in the preoperative planning of more complex cavopulmonary connections in candidates for the Fontan procedure.

More than one-half of patients with isomerism have bilateral superior caval veins.⁶ When bilateral superior caval veins are found, colour flow imaging is helpful in establishing their precise point of junction with the atrium. In all patients with right isomerism, and in over half with left isomerism, bilateral superior caval venous drainage is directly to each atrial roof. In left isomerism, one superior caval vein can also drain through the coronary sinus. This finding is again readily made by cross sectional and colour flow imaging. Failure to identify bilateral drainage to the roof of each atrium will lead to severe desaturation if biventricular repair is performed without appropriate baffling of all systemic venous return to the appropriate atrium. The echocardiographic recognition of bilateral superior caval veins is also of importance for the majority of patients with isomerism in whom it is not possible to achieve biventricular repair. Increasingly, such patients undergo intermediate palliation by construction of a bidirectional superior cavopulmonary anastomosis prior to completion of the Fontan circulation.

Equally important is knowledge of pulmonary venous connections. If left isomerism is suspected, then bilateral drainage to each atrium can be anticipated in over half the hearts, with direct drainage to one or the other atrium in the remaining ones. This can usually be well demonstrated in subcostal and apical four-chamber views. The characteristic absence of obstruction to pulmonary venous return can be confirmed by colour flow and pulsed wave Doppler interrogation. In the setting of right isomerism, pulmonary venous drainage is more complex. Obstruction must be ruled out in each case irrespective of whether the pulmonary veins drain above or below the diaphragm. We have observed obstruction at the site of insertion of pulmonary veins directly to the superior caval vein, at the junction of a vertical vein to the brachiocephalic vein, and, of course, where drainage is infradiaphragmatic. Rarely, obstruction may even be observed with cardiac connection of the anomalous pulmonary venous return in right isomerism. A vertical vein can be compressed externally, and can take a retrobronchial path in right isomerism.⁹³ The principles of echocardiographic identification of anomalous pulmonary venous return, and recognition of its obstruction, are the same as for hearts with lateralised atria (see Chapter 24). Despite the presence of decreased pulmonary blood flow in right isomerism, we have noted the characteristic disturbance of colour flow and pulsed Doppler in all patients that we have studied with obstructed pulmonary venous return.

In general, the evaluation of the intracardiac abnormalities poses few problems for the experienced echocardiographer. All the individual intracardiac anomalies seen in patients with isomeric atrial appendages have been observed in those with usual or mirror-imaged arrangement, and their echocardiographic features have been described in other chapters. These will not be discussed further here. It should be noted, nonetheless, that direct visualisation of the atrial appendages can still be difficult when using the transthoracic windows, albeit that it is

Figure 22-21 The typical arrangement of the great vessels, as seen in the echocardiographic short-axis view of the upper abdomen. **A**, The inferior caval vein is to the right (and slightly anterior) and the aorta to the left of the spine. This feature is an inferential guide to usual atrial arrangement. **B**, The opposite pattern is observed in mirror-image atrial arrangement, sometimes referred to as situs inversus. **C**, In this patient, the aorta and the inferior caval vein are both to the left of the spine, with the venous channel in anterior position. This is highly suggestive of right isomerism. **D**, The typical arrangement of the abdominal great vessels in left isomerism. The aorta and the venous channel are to the same side of the spine (compare with **C**), but now with the vein in posterior position. This is interruption of the inferior caval vein in the setting of left isomerism and the venous channel continues to the azygos venous system (see text for further discussion).

possible on occasion to recognise with certainty isomeric appendages of left morphology (Fig. 22-22). With transoesophageal echocardiography, it is possible better to visualise the atrial appendages, and to make direct assessment of their morphology, distinguishing the normal appendages one from the other (Fig. 22-23), and recognising isomeric appendages when present (Fig. 22-24). Due to its invasive nature, this is usually only performed if trans-thoracic echocardiography proves inadequate to make a comprehensive anatomical diagnosis. When performed,

excellent visualisation of the atrial appendages is obtained from the oesophageal and gastric windows, allowing accurate determination of atrial arrangement.^{94,95}

Cardiac Catheterisation and Angiography

Echocardiography has obviated the need for cardiac catheterisation in the majority of neonates suspected as having isomerism of the atrial appendages. Cardiac catheterisation should be reserved for those rare instances in which echocardiographic interrogation has failed to provide the surgeon with sufficient information for planning of the initial palliative procedure. The operator should enter the catheterisation laboratory with specific questions in mind. It is not justified in the current era to perform a complete study on these sick infants if information sought has already been obtained by echocardiography. For example, if the source of pulmonary blood flow has not been adequately delineated in a neonate with right isomerism and pulmonary atresia, aortography will suffice to rule out systemic-to-pulmonary collateral arteries. The approach to catheterisation, therefore, will depend on the information required, and will be guided by the knowledge already obtained from the echocardiogram. In the presence of left isomerism with interrupted inferior caval vein, it may be easier to manoeuvre the catheter around the heart when access is obtained from the internal jugular vein. Access to the pulmonary arteries may be particularly awkward when catheterisation is performed from the femoral vein. This is because of the sharp angulation of the catheter as it passes from the azygos venous system to the superior

Figure 22-22 This precordial echocardiogram from a patient with atrioventricular septal defect and right hand ventricular topology reveals the presence of isomeric left atrial appendages. AV, atrioventricular.

Figure 22-23 These transoesophageal images distinguish clearly the morphology of the right (A) as opposed to the left (B) atrial appendages.

caval vein and atrium (Fig. 22-25). In right isomerism, every attempt should be made to delineate the pulmonary venous connections if these have not been fully established non-invasively. This may be necessary when complex patterns of drainage are present, for example, mixed anomalous pulmonary venous connection. In practical terms, the site of drainage of pulmonary venous return is less important than the presence of obstruction in the setting of common mixing and decreased pulmonary blood flow. The initial palliation for the majority of these infants will be construction of a systemic-to-pulmonary shunt. Surgical attention to the pulmonary venous drainage will usually be required in the neonatal period only if obstruction is present. In right isomerism, the pulmonary trunk cannot usually be entered from the ventricular mass. Placement of a catheter across the arterial duct for the purposes of pulmonary arteriography is not advisable in the duct-dependent circulation. Ventriculography and aortography often provide poor

visualisation of the pulmonary venous return. Whenever possible, therefore, the pulmonary venous channels should be entered directly via their site of drainage. This will allow direct angiography of the pulmonary venous pathways (Fig. 22-26). A more complete haemodynamic and angiographic evaluation of patients with isomeric atrial appendages is usually performed in preparation for further surgery sometime after the initial surgical palliation. Since many patients will be unsuitable for biventricular repair, attention will focus on those factors important for planning of partial or total cavopulmonary connections. Angiographic delineation of all systemic and pulmonary venous return should be completed at this time. In addition, selective injection of agitated saline in each pulmonary artery, combined with

Figure 22-24 This transoesophageal image from a patient with double inlet right ventricle through a common atrioventricular valve shows broad-based morphologically right atrial appendages arising bilaterally from the common atrial chamber.

Figure 22-25 This lateral angiogram shows the characteristic features of interruption of the abdominal inferior caval vein, with continuation through the azygos (Az) venous system. The azygos vein is seen joining the left superior caval vein (LSCV), which drains to a morphological left atrium (LA).

Figure 22-26 In this patient with right isomerism, it was possible to manoeuvre a catheter via the umbilical vein and the venous duct into the portal venous system to show totally anomalous infradiaphragmatic pulmonary venous connection.

Figure 22-27 The magnetic resonance images show (A) the bilaterally short and eparterial bronchuses typical of right isomerism, and (B) the bilaterally long and hyperarterial bronchuses, typical of left isomerism. (Courtesy of Dr Sameh Tadros, Children's Hospital of Pittsburgh, Pittsburgh, Pennsylvania.)

cross sectional echocardiography, is prudent for all patients being staged towards cavopulmonary repair. This, along with determination of pulmonary venous oxyhaemoglobin saturation, will document the presence of pulmonary arterio-venous malformations. A detailed account of the angiographic evaluation of patients with isomerism has been provided by Freedom and colleagues.⁹⁶

Magnetic Resonance Imaging

Resonance imaging can provide accurate delineation of the thoracic, cardiac, and vascular abnormalities seen in patients with isomeric appendages.^{97–100} As might be anticipated, the technique is particularly good at demonstrating the presence of right (Fig. 22-27A) or left (see Fig. 22-27B) bronchial isomerism. It is also possible to recognise absence of the spleen (Fig. 22-28). We anticipate that the images should also reveal the presence of bilaterally symmetrical appendages of either right or left morphology, particularly when taking note of the presence or absence of venous channels within the atrioventricular junctions. As well as revealing the patterns of coronary venous return, the technique is also able to demonstrate the specific patterns of systemic and pulmonary venous return. In the setting of cyanotic disease, magnetic resonance imaging can provide details of the sources of flow of blood to the lungs, and the anatomy and size of the pulmonary arteries. Resonance imaging may be particularly useful in obviating the need for cardiac catheterisation in critically sick infants prior to initial surgical intervention.¹⁰⁰ It also provides confirmation of splenic morphology, if present. Serial imaging may prove very useful during long-term follow-up and prior to

Figure 22-28 This magnetic resonance image shows absence of the spleen in a patient known to have isomeric right atrial appendages. (Courtesy of Dr Sameh Tadros, Children's Hospital of Pittsburgh, Pittsburgh, Pennsylvania.)

each planned surgical intervention. Computed tomography may also be useful in the non-invasive evaluation of children with heterotaxy syndromes.¹⁰¹ The exposure to radiation is a disadvantage compared to resonance imaging,

especially for serial studies and rapid heart rates complicate the acquisition of good images.

Investigation of Splenic State

The presence of multiple spleens is an anatomical curiosity of little clinical significance, and splenic function is generally preserved. The absence of the spleen (see Fig. 22-28), or severe splenic hypoplasia, in contrast, is of major clinical importance, since this results in increased risk of overwhelming sepsis. This risk appears greatest when absence of the spleen is congenital.¹⁰² Since there are many documented instances of discordance between bronchio-atrial arrangement and splenic state, all infants with suspected isomerism should undergo evaluation for possible absence of the spleen.¹⁰³ In the absence of a spleen, Howell-Jolly bodies are usually present on a smear of peripheral blood. Their presence is highly suggestive of asplenia.^{104,105} On occasion, these bodies can be found in the blood of patients with normal spleens,¹⁰⁶ especially in the neonatal period.¹⁰⁷ A variety of imaging modalities has been reported to be useful in the identification of asplenia.¹⁰³ These include cross sectional echocardiography,¹⁰⁷ radionuclide scintigraphy,¹⁰⁸ and computed tomography or magnetic resonance imaging.^{100,109}

MANAGEMENT

The treatment of patients with isomerism will be determined by the nature and severity of the associated cardiac and extracardiac lesions. Some patients with left isomerism may have no additional cardiac lesions, and they will require no treatment. Patients with left isomerism in general have less severe cardiac malformations than those with right isomerism and, hence, more chance of corrective surgery. Those with right isomerism usually require palliative surgery in the neonatal period, and very few will progress to biventricular repair. Cardiac interventions, therefore, will be geared towards subsequent completion of the Fontan circulation. It is axiomatic, nonetheless, that patients are treated on their own merits.

Medical Management

Many infants with right or left isomerism will present severely ill as a result of duct-dependent congenital cardiac disease. The severely cyanotic infant will usually have right isomerism with severe obstruction in the pulmonary outflow tract. These patients are usually easily stabilised by treatment with prostaglandin E₁. When there is associated severe obstruction to pulmonary venous return, no medical therapy other than standard supportive measures will help, and early surgery is indicated. Preoperative stabilisation with extracorporeal membrane oxygenation has been recommended by some groups. Left isomerism is most likely to present in the neonatal period when there is severe obstruction of the left heart. Cardiac failure and shock are managed in the standard fashion as for severe left-sided obstruction with usual atrial arrangement. Occasionally, hydropic fetuses with left isomerism, severe bradycardia, and severe atrioventricular valvar regurgitation will survive to term. This constellation of findings is usually lethal. It is questionable whether attempts at emergency pacing are worthwhile, especially when there is associated complex cardiac disease.

Since neonates with isomerism are generally referred early in life to tertiary centres, the paediatric cardiologist often must to assume responsibility for complete evaluation of the infant. As we have stressed, isomerism is a fundamental disorder of lateralisation, and is often associated with important extracardiac abnormalities. Careful evaluation of all systems is mandatory before referral for cardiac surgery. Renal ultrasound is probably warranted on a routine basis because of the high incidence of abnormalities of the renal tracts, as is cerebral ultrasound. Routine abdominal ultrasound, with focus on the biliary tree, is warranted even in the absence of jaundice in infants with left isomerism, since early diagnosis of extrahepatic biliary atresia will strongly influence overall management of these infants. Persistent vomiting in the neonatal period should raise the suspicion of upper gastrointestinal obstruction owing to duodenal atresia or compression. All families should be told of the risk of late intestinal obstruction caused by gastrointestinal malrotation or gastric volvulus.¹¹⁰⁻¹¹²

As already discussed, the state of the spleen should be established in all patients. When right isomerism is diagnosed, the presence of Howell-Jolly bodies on the peripheral blood film suffices to make a presumptive diagnosis of asplenia. If Howell-Jolly bodies are not observed, absence of the spleen should still be assumed until imaging studies have confirmed its presence. When left isomerism is diagnosed, the absence of Howell-Jolly bodies on several blood films can be considered as adequate evidence of functioning splenic tissue, and routine radionuclide scintigraphy or computed tomography are not warranted. When congenital absence of the spleen is diagnosed, there is a lifelong risk of overwhelming infection. Although infection is most commonly caused by polysaccharide-encapsulated bacteria, such as *Streptococcus pneumoniae* and *Haemophilus influenzae*, infection with Gram-negative organisms may predominate in the first 6 months of life.¹¹⁰ When septicaemia develops in the asplenic patient with congenital cardiac disease, the clinical course is often fulminant.^{113,114} The family members of such infants should be made aware of the risk of fatal sepsis, and should seek medical attention early when fevers develop so that blood cultures can be drawn and antibiotics started if there is no clear evidence of viral illness. Prophylactic antibiotics should be given from the time of diagnosis. Amoxicillin is often recommended for the first 5 years, after which time penicillin can be substituted. This should be continued for life. Pneumococcal vaccine should be given, although its immunogenicity in this setting is unclear.¹¹⁵ Conjugate vaccines for *Haemophilus influenzae* type b do appear to be effective in patients with congenital asplenia.¹¹⁶ This should be given in infancy according to standard protocols.¹¹⁷ Whenever possible, immunogenicity of polysaccharide vaccines should be confirmed serologically.

Surgical Management

All cardiac operative procedures for patients with isomerism are palliative in nature, since normal anatomy is never achieved, and late complications, such as disturbances of rhythm, may develop. Recent experience in Osaka, nonetheless, shows that surgical results are improving, albeit better in those with left compared to right isomerism (Fig. 22-29). In this section, we use the term corrective for those procedures that result in complete, or near complete, separation of the circulations. Approximately two-thirds of patients

Figure 22-29 The graph shows the results of surgical treatment at the National Cardiovascular Centre, Osaka, Japan, for patients with left as compared with right isomerism.

with left isomerism have anatomy suitable for biventricular repair. Most commonly such patients have atrioventricular septal defects, with anomalies of systemic and pulmonary venous return, but with concordant ventriculo-arterial connections. Repair is achieved using standard techniques with appropriate baffling of anomalous venous return.^{118,119} After biventricular repair, however, it is frequent to encounter progressive valvar regurgitation, particularly across the left atrioventricular valve. This often results in the need for reoperation, as does recurrent subaortic stenosis, which is commoner in those with left isomerism than in the setting of usual atrial arrangement. In the recent experience at Osaka, one-fifth of patients undergoing repair of atrioventricular septal defect in the setting of left isomerism required reoperation on the left atrioventricular valve, and one-sixth needed further surgery to the left ventricular outflow tract. In contrast, reoperation was necessary for 7% of those having usual atrial arrangement, and only for repair of the left atrioventricular valve. These differences were highly statistically significant, and reflect the subtle morphologic variations found in those with left isomerism.¹²⁰

The anomalies observed in right isomerism are rarely amenable to biventricular repair, even when two well-balanced ventricles are present. Rare reports of biventricular repair of right isomerism do exist.^{121–124} Almost all patients with right isomerism, and many patients with left isomerism, will require initial surgical palliation in the neonatal period or during early infancy. Corrective procedures may be possible at a later date in selected patients. Little data is available to indicate what proportion of newborn infants with isomerism will go on to achieve complete separation of the systemic and pulmonary circulations.

In right isomerism, the initial need is usually to increase the flows of blood to the lungs. Placement of a systemic-to-pulmonary shunt should only be performed when it is certain that there is no obstruction to pulmonary venous return. We believe that careful evaluation of the patient, taking note of the chest radiograph and the echocardiogram, should allow for the preoperative diagnosis of obstructed pulmonary venous return. This should avoid the high mortality that will occur when shunts are constructed in the presence of undiagnosed obstructed pulmonary venous return.^{78–80} When obstruction to pulmonary venous return is present, the outcome is much less favourable, even if the diagnosis is made prior to construction of the shunt.⁷⁹ This reflects the difficult post-operative course of patients undergoing combined repair of obstructed pulmonary veins with

construction of a systemic-to-pulmonary shunt under cardiopulmonary bypass. This combination was traditionally considered lethal, and many infants were not offered surgery. More recently, successful initial palliation has been achieved by creating an anastomosis between the pulmonary venous confluence and the atrium, and constructing a systemic-to-pulmonary arterial shunt.¹²⁵ There is some evidence for improving outcomes with this constellation, although long-term outcomes appear poor. Note should also be taken of the fact that, in those with right isomerism, one-tenth have mixed totally anomalous pulmonary venous connections. If unrecognised, this can also complicate the post-operative course.

The palliative procedures required for neonates and infants with left isomerism are diverse and reflect the highly variable anatomy. Some infants present with complex disease associated with subpulmonary obstruction. They are initially managed by construction of a systemic-to-pulmonary shunt as for those with right isomerism. In other patients, a univentricular atrioventricular connection may be associated with unobstructed pulmonary blood flow, and banding of the pulmonary trunk may be indicated. More commonly, complex left heart obstruction may be present. When this is associated with left ventricular hypoplasia, severe subaortic stenosis or a diminutive aorta, a neonatal Norwood approach will be required if palliation is to be attempted. This will not be feasible if there is significant regurgitation of the common atrioventricular valve.

For almost all patients with right isomerism, and for many with left isomerism, biventricular repair will not be feasible, and all palliations are then staging procedures towards a Fontan-type repair. Increasingly, patients with isomerism will be staged via one or more intermediate procedures, usually involving a superior cavopulmonary anastomosis or its physiological equivalent, the hemi-Fontan procedure. When bilateral superior caval veins are present, bilateral bidirectional superior cavopulmonary anastomoses are performed. It has been argued that bidirectional superior cavopulmonary connection, augmented by an additional small source of pulsatile flow to the lungs, may be the optimal final procedure for selected patients with isomerism, who are at high risk for completion of a total cavopulmonary connection.¹²⁶ When there is interruption of the inferior caval vein, bidirectional superior cavopulmonary anastomosis will result in all systemic venous return being diverted to the lungs except for that returning from the hepatic veins, which drains directly to the atrium. This procedure, the so-called Kawashima operation,¹²⁷ has been widely used in patients with left isomerism. In many respects, the end result is similar to completion of the fenestrated Fontan circulation incorporating a fenestration. The early clinical course is usually excellent. Important late problems, nonetheless, have been observed. First, venovenous collaterals may develop between the systemic venous system above the diaphragm, which is at relatively high pressure, and the low pressure hepatic venous system below the diaphragm. This can result in steal of desaturated blood away from the lungs to the hepatic veins, and then to the atrium. This can then result in progressive cyanosis.¹²⁸ A similar phenomenon has been observed when large venous collaterals drain from the inferior caval vein through the liver to the hepatic veins, diverting systemic venous blood to the pulmonary venous atrium, and away from the lungs.¹²⁹ Such a right-to-left shunt from

the inferior caval vein can also occur in right isomerism after completion of the Fontan circuit if any hepatic vein remains draining to the low pressure pulmonary venous atrium.¹³⁰ A second cause of progressive cyanosis after the Kawashima procedure is the development of pulmonary arterio-venous malformations. Patients with multiple spleens and left isomerism seem particularly prone to this complication.^{131,132} There is increasing evidence that a hepatic factor may be important in preventing this development.¹³³ We believe that the indications for the original Kawashima procedure require careful re-evaluation. Whenever possible, the hepatic venous return should be diverted to the pulmonary arteries via a baffle or conduit should a bidirectional superior cavopulmonary anastomosis be performed beyond infancy in patients with interruption of the inferior caval vein. Thus, it is better to achieve the Fontan circulation in one-stage primary fashion, or in two stages with a short interval between them. An alternative surgical technique, recently described, is to combine the Kawashima procedure with a direct connection of the hepatic veins to the azygos venous system.¹³⁴ Late incorporation of the hepatic venous return to the pulmonary arteries after development of pulmonary arterio-venous malformations has been shown to result in their regression, and relief of cyanosis.^{135,136}

The almost universal presence of anomalies of veno-atrial connections creates extra problems for complete separation of the systemic and pulmonary circulations. Cardiac surgeons, nonetheless, have risen to the challenge, and it is now technically feasible to achieve this separation in almost all cases. A variety of novel modifications of the total cavopulmonary connection have been devised to achieve this result.^{137–139} Introduction of the extracardiac conduit technique for construction of the Fontan circuit has particular benefits for this group of patients with anomalies of systemic and pulmonary venous return, since the need for complex intra-atrial baffles and tunnels is obviated.¹⁴⁰ Initial results of the Fontan procedure in patients with isomerism were significantly inferior to those for patients with lateralised arrangement undergoing similar procedures.^{141,142} In recent years, a number of groups have reported significantly improved results.^{125,140,143–145} Careful pre-operative delineation of anatomy, improved selection of patients, enhanced surgical experience, newer surgical techniques, and improved post-operative care probably account for the improved outcomes.¹⁴⁶

When attempting to complete the Fontan circulation by means of a total cavopulmonary connection, another compromising factor is the orientation of the ventricular apex relative to the junction between the inferior caval vein and the atrial chambers. When the apex is juxtaposed to the cavo-atrial junction, the channel to be reconstructed towards the pulmonary arteries needs to be placed so as to avoid compression by the ventricular mass. Particular care is required in design of the channel in presence of independent drainage of the hepatic veins. It is always possible successfully to complete the Fontan circulation, but surgeons must take care to avoid the various potential anatomical pitfalls.

Transplantation has also been advocated as an option for treatment for selected infants and children.^{147,148} This would seem most appropriate when other palliative procedures are contraindicated. This might include infants with severe atrioventricular valvar regurgitation associated with complex cardiac disease. Complex anomalies of systemic

and pulmonary venous return do not preclude the possibility of successful orthotopic cardiac transplantation, though pulmonary venous obstruction may develop after transplantation.¹⁴⁷ There is insufficient data at the present time to know how absence of the spleen will impact on the occurrence of rejection and infection. The main limitation to transplantation for this group of infants is the low availability of donors. Furthermore, there is growing evidence that neonatal recipients are not immune from lethal long-term complications of transplantation, in particular the development of coronary arterial disease.¹⁴⁹

PROGNOSIS

It is hard to define the prognosis for infants with isomerism, since there is little longitudinal follow-up data. The natural history for patients presenting in infancy is very poor, with death occurring in the majority in the first year of life.³⁸ Surgical reports provide limited information about overall prognosis, since patients are preselected as suitable surgical candidates. Longitudinal population-based studies are required to assess outcome from presentation through all stages of surgical reconstruction. They must include all causes of death, whether cardiac or non-cardiac.¹⁷

Recent advances in medical management, and in particular the improvements in cardiac surgical skills and techniques occurring throughout the world, are likely to result in improvement in survival for these infants. Key factors limiting success at this time are the presence of moderate or greater atrioventricular valvar regurgitation, generally with a common atrioventricular valve, and the development or persistence of recurrent obstruction of a pulmonary venous confluence, or intrinsic pulmonary venous stenosis, after initial surgical palliation.¹⁵⁰ There is also a high incidence of atrial arrhythmias in this population, both early and late after completion of the Fontan circulation.^{144,145,151} As would be expected, ongoing attrition and morbidity among these children can be anticipated late after conversion to Fontan physiology.^{140–146} Encouragingly, though, the Pediatric Heart Network of the National Heart, Lung, and Blood Institute of the National Institutes of Health has recently shown that exercise performance, and functional state of health, are comparable between those surviving with the Fontan circulation irrespective of the presence or absence of heterotaxy.¹⁵² While surgical data suggests improving outcomes, nonetheless, other findings continue to suggest an overall poor prognosis for infants with isomerism when evaluated from the time of birth.^{17,153} These disorders remain one of the greatest challenges for paediatric cardiologists and congenital cardiovascular surgeons.¹⁵⁴

ANNOTATED REFERENCES

- Ivemark B: Implications of agenesis of the spleen in the pathogenesis of conotruncus anomalies in childhood: An analysis of the heart; malformations in the splenic agenesis syndrome, with 14 new cases. *Acta Paediatr Scand* 1955;44(Suppl 104):1–110.
This landmark paper was one of the first to recognise the association between splenic status, complex congenital cardiac disease, and abnormal arrangement of the viscera, focusing on the tendency to symmetry, hence, his description of 'asplenia, a teratologic syndrome of visceral symmetry'.
- Putschar WGJ, Mannion WC: Congenital absence of the spleen and associated anomalies. *Am J Clin Pathol* 1956;26:429–470.

In the year following Ivemark's landmark study, Putschar and Mannion provided further evidence of the entities that we now call left and right isomerism. They referred to a 'symmetrical situs [that] sometimes exists, exhibiting symmetrical rightness or leftness on both sides'. Although terminology has evolved, this is probably the most eloquent description of isomerism in the historical literature.

- Van Mierop LHS, Wigglesworth FW: Isomerism of the cardiac atria in the asplenia syndrome. *Lab Invest* 1962;11:1303–1315.

This study was the first carefully to describe the presence of two appendages both of right-sided morphology, along with duplication of sinus nodes. This confirmed the reality of isomerism of the atrial appendages.

- Moller JH, Nakib A, Anderson RC, Edwards JE: Congenital cardiac disease associated with polysplenia: A developmental complex of bilateral 'left-sidedness.' *Circulation* 1967;36:789–799.

This report was the first to describe in a large number of patients the relationship between the presence of multiple spleens, congenital cardiac disease, and the presence of left isomerism, which they described as bilateral left-sidedness.

- Uemura H, Ho SY, Devine WA, Anderson RH: Analysis of visceral heterotaxy according to splenic status, appendage morphology, or both. *Am J Cardiol* 1995;76:846–849.
- Uemura H, Ho SY, Devine WA, et al: Atrial appendages and venoatrial connections in hearts from patients with visceral heterotaxy. *Ann Thorac Surg* 1995;60:561–569.

These two reports are from a series of carefully performed studies that define the spectrum of morphology in hearts from patients with visceral heterotaxy. The authors emphasise that it is the arrangement and extent of the pectinate muscles that is the most constant feature of the morphology of the appendages, permitting distinction of the appendages as being of left or right morphology. The reports also provide precise details of venoatrial arrangements, and emphasise that cardiac morphology should not be inferred from splenic status.

- Layton WM, Jr: Heart malformations in mice homozygous for a gene causing situs inversus. *Birth Defects Orig Artic Ser* 1978;14:277–293.

This report describes the first vertebrate animal model of abnormal lateralisation to be studied in detail. Initially it was thought to be a model of mirror-imaged arrangement, or so-called situs inversus.

- Seo J-W, Brown NA, Ho SY, Anderson RH: Abnormal laterality and congenital cardiac anomalies: Relations of visceral and cardiac morphologies in the iv/iv mouse. *Circulation* 1992;86:642–650.

This was the first detailed evaluation of the cardiovascular anomalies in the iv/iv mouse model of abnormal lateralisation. Contrary to prior reports, the authors observed that some animals had clear evidence of isomeric atrial appendages, either left or right, and associated cardiac and venous abnormalities. This demonstrated that the iv/iv model is more complex than a model of usual and mirror-imaged atrial arrangement.

- Kawashima Y, Kitamura S, Matsuda H, et al: Total cavopulmonary shunt operation in complex cardiac anomalies: A new operation. *J Thorac Cardiovasc Surg* 1984;87:74–81.

The initial description by Kawashima and colleagues of four patients with azygos or hemiazygos continuation of the inferior caval vein who underwent a direct superior caval-to-pulmonary artery anastomosis. This operation has been widely used in patients with left isomerism as definitive repair. Although the early results are generally very good, serious late complications include veno-venous collaterals draining from above the diaphragm to the hepatic veins, and the development of pulmonary arterio-venous malformations. Both complications have led to late severe cyanosis.

- McElhinney DB, Kreutzer J, Lang P, et al: Incorporation of the hepatic veins into the cavopulmonary circulation in patients with heterotaxy and pulmonary arteriovenous malformations after a Kawashima procedure. *Ann Thorac Surg* 2005;80:1597–1603.

The largest report to date emphasising that incorporation of the hepatic veins into the cavopulmonary circulation can reverse pulmonary arteriovenous malformations after the Kawashima procedure. This provides further evidence for a hepatic factor.

- Bartz PJ, Driscoll DJ, Dearani JA, et al: Early and late results of the modified Fontan operation for heterotaxy syndrome: 30 years of experience in 142 patients. *J Am Coll Cardiol* 2006;48:2301–2305.

A recent large single-centre review of outcomes after the Fontan procedure for patients with heterotaxy, emphasising improving outcomes in the modern era.

- Atz AM, Cohen MS, Sleeper LA, et al, for the Investigators of the Pediatric Heart Network: Functional state of patients with heterotaxy syndrome following the Fontan operation. *Cardiol Young* 2007;17(Suppl 2):44–53.

The first study to address functional state and quality of life issues after construction of the Fontan circulation in patients with visceral heterotaxy. Atrial arrhythmias were more common in the patients with heterotaxy. Exercise performance, and results from health state questionnaires, did not differ between patients with and without heterotaxy.

- Freedom RM, Jaeggi ET, Lim JS, Anderson RH: Hearts with isomerism of the right atrial appendages—one of the worst forms of disease in 2005. *Cardiol Young* 2005;15:554–567.

This review by the late Robert Freedom and his colleagues emphasises how prognosis remains very poor for patients with right isomerism, despite improved surgical outcomes in some reports. The review emphasises that outcomes are best assessed from population data, starting from the time of birth, or even from time of diagnosis in fetal life. Surgical series may distort true outcomes by analysis of highly selected populations, such as those deemed suitable for conversion to the Fontan circulation.

CHAPTER 23

Anomalous Systemic Venous Return

JEFFREY F. SMALLHORN and ROBERT H. ANDERSON

In this chapter, we deal with abnormalities of position and connection of the major systemic venous channels that drain to the heart, and also with abnormal persistence of the valves of the embryonic systemic venous sinus. Many of these anomalies are incidental findings, having little haemodynamic significance. They may, however, complicate interventional procedures, and they may be associated with other more important congenital cardiac anomalies. A consideration of the morphogenesis of the normal systemic venous system is helpful in understanding the wide variety of systemic venous anomalies that exist. We will review briefly the presumed embryology of the systemic venous system, therefore, before considering the individual anomalies and their clinical significance.

MORPHOGENESIS OF THE SYSTEMIC VENOUS SYSTEM

Normal venous development is a process of progressive appearance of a series of paired venous structures, development of anastomotic channels between them, and the eventual selective regression of certain segments. The systemic venous tributaries are initially bilaterally symmetrical. They join together on each side, opening to the developing heart tube through paired channels known as the sinus horns. When first seen joining the developing atrium (Fig. 23-1), there are no anatomical landmarks that permit distinction of a separate segment as a sinus venosus, such as exists in the hearts of lower vertebrates.¹ Initially, three major venous channels drain into each horn, namely the omphalomesenteric or vitelline veins medially, the umbilical veins in the middle, and the common cardinal veins laterally (Fig. 23-2). Each common cardinal vein is formed by the union of the superior and inferior cardinal veins, which drain the cephalic and caudal regions of the embryo, respectively. Concomitant with development of anastomotic channels between the right- and left-sided venous channels formed throughout the embryo, there is preferential flow to the right-sided structures. The left horn then rotates beneath the atrioventricular junction, moving around the fulcrum provided by the developing pulmonary vein, so as to open in the right side of the developing atrial component of the heart tube (Fig. 23-3). It is only at this stage, which is also the period of initial formation of the primary atrial septum, that it becomes possible to recognise the valvar structures marking the junction between the systemic venous tributaries and the developing morphologically right atrial chamber. These structures serve as the valves of the systemic venous sinus, and are often described simply as the venous valves (see Fig. 23-3). There then

follows gradual regression of the left-sided vitelline and cardinal veins, with increasing prominence of the right sinus horn. Eventually, the entirety of the systemic venous sinus within the confines of the valves becomes incorporated as the smooth-walled venous component of the morphologically right atrium, with the opening of the right common cardinal vein becoming the orifice of the superior caval vein, and that of the right vitelline vein becoming the entrance of the inferior caval vein. The mouth of the left sinus horn then persists as the orifice of the coronary sinus (Fig. 23-4).

The initial anastomotic connection between the right and left cranial cardinal veins enlarges, and becomes the left brachiocephalic vein, often illogically termed the innominate vein. What is the purpose of having an unnamed vein? In the process of normal development, the left superior cardinal vein below this point gradually regresses, with its remnant forming the ligament and oblique vein of Marshall (Fig. 23-5). With ongoing development, there are further changes in the valves of the systemic venous sinus. The right-sided valve is prominent during embryonic life, while the left valve is less prominent, eventually fusing with the atrial septum. The right valve subsequently also regresses

Figure 23-1 This scanning electron micrograph shows the developing atrial component of the mouse heart. Already the left sinus horn is diminished in size relative to the right horn, but no discrete structures mark the junction of the systemic venous tributaries with the heart. Note also that, as yet, there is no canalisation of the pulmonary vein within the dorsal mesocardium, nor indeed any formation of the lungs. (Courtesy of Professor Nigel Brown, St George's Medical University, London, United Kingdom.)

Figure 23-2 The cartoon shows the initial arrangement of the venous channels draining via the sinus horns to the atrial component of the developing heart. LICV, left inferior caval vein; LSCV, left superior caval vein; LUV, left umbilical vein; LVV, left vitelline vein; RICV, right inferior caval vein; RSCV, right superior caval vein; RUV, right umbilical vein; RVV, right vitelline vein.

for its most part, except for portions which persist as folds related to the orifices of the inferior caval vein, the Eustachian valve, and the coronary sinus, the Thebesian valve.

The development of the pulmonary venous system is also of significance, considering the occasional co-existence of anomalies of pulmonary and systemic venous drainage. The developing lungs are derived from the primitive foregut. They share their early vascular supply with the gut via a splanchnic plexus.² This plexus initially drains the intra-parenchymal pulmonary tissues to the cardinal venous system. With normal development, these connections are lost as the pulmonary vein itself canalises in the dorsal mesocardium and gains entrance to the developing morphologically left atrium.³

Figure 23-3 This scanning electron micrograph shows the developing right atrium subsequent to incorporation of the systemic venous sinus and formation of the venous valves. It shows the course of the left sinus horn through the developing left atrioventricular junction. The pulmonary ridges can also be seen at the base of the primary atrial septum, albeit that the opening of the solitary pulmonary vein between them is not visible. (Courtesy of Professor Nigel Brown, St George's Medical University, London, United Kingdom.)

Figure 23-4 The cartoon shows the arrangement of the systemic venous tributaries subsequent to the formation of the anastomoses that permit the systemic venous sinus to become incorporated into the right side of the developing atrial component of the heart tube. ICV, inferior caval vein; LUV, left umbilical vein; SCV, superior caval vein.

Figure 23-5 The cartoon shows the initial course of the left-sided cardinal vein draining to the left sinus horn. As shown, this channel usually regresses, but can persist as the left superior caval vein (LSCV). Its remnant in the posterior wall of the left atrium is the oblique vein and the ligament of Marshall. ICV, inferior caval vein; SCV, superior caval vein.

Figure 23-6 The cartoon shows the formation of the subcardinal venous system, which initially drains bilaterally into the cardinal system of veins.

Initially, therefore, there are three systemic venous systems developing within the embryo, namely the vitelline, umbilical, and cardinal systems (see Fig. 23-2). The vitelline system largely becomes a vascular network draining the liver. These channels are predominant on the right side of the embryo, maintaining their connection to the right side of the systemic venous sinus through structures known as the hepatocardiac channels. As we have seen, it is the right-sided vitelline vein that ultimately becomes the terminal post-hepatic portion of the inferior caval vein (see Fig. 23-4). The umbilical veins are also paired structures when first seen. They lose their connection to the venous sinus, and anastomose to the hepatic sinusoids. The right-sided umbilical vein then regresses, while the left umbilical vein enlarges to become the only channel bringing blood from the placenta to the embryo, forming an anastomosis with the hepatocardiac channel which becomes the venous duct.

Further important changes occur within the developing abdominal region of the embryo that underscore normal and anomalous formation of the inferior caval vein. By the fifth week of gestation, paired subcardinal veins arise medial to the inferior cardinal veins, serving initially to drain the forming urogenital sinuses. When traced cranially, these subcardinal veins empty into the caudal cardinal veins on both sides (Fig. 23-6). Anastomotic channels then develop between the two subcardinal veins, as well as between the right subcardinal and hepatocardiac channels. It is the right subcardinal vein that becomes predominant, developing into the infrahepatic segment of the inferior caval vein, and joining this segment to the right vitelline vein, which forms the entrance to the morphologically right atrium. With continued growth of the trunk of the embryo, yet another system

Figure 23-7 Formation of the subcardinal anastomotic channels, and the sacrocardinal plexus, which contribute to formation of the renal and suprarenal venous systems along with the abdominal inferior caval vein. Note also, however, the formation of the supracardinal venous system, which forms anastomotic channels between the subcardinal and common cardinal systems within the developing thorax.

of veins, the sacrocardinal veins, arises dorsal and caudal to the inferior cardinal system. Anastomotic channels between the subcardinal and sacrocardinal systems on the right side will form the renal segment of the inferior caval vein, while the distal portions of the right sacrocardinal vein enlarge and become its most inferior portion (Fig. 23-7).

Concomitant with these developments of the paracardinal systems, and apart from their most proximal portions, the inferior cardinal veins themselves gradually involute. This involution occurs concomitant with the transformation of the supracardinal venous system into the azygos and hemiazygos veins on the right and left sides, respectively, which terminate cranially in the right cardinal venous system (Fig. 23-8). The definitive inferior caval vein, therefore, has multiple embryological origins. Its terminal suprahepatic portion is derived from the right vitelline vein. The infrahepatic segment arises from the right subcardinal vein, the intermediate segment from the anastomotic channels initially developed between the subcardinal and sacrocardinal veins, and the most inferior segment from the right sacrocardinal vein. The azygos and hemiazygos veins are derived from the supracardinal system (Fig. 23-9). Should there be abnormal development of these multiple abdominal venous channels, it is possible for the supracardinal venous system to become dominant. This then results in the venous return from the lower abdomen returning through the azygos system of veins to either the right- or left-sided superior caval vein. The inferior caval vein is then itself interrupted between the abdominal and hepatic segments, the hepatic segment draining only the blood from the liver and the portal venous system back to the heart.

Figure 23-8 With further development of the abdominal venous system, there is regression of the cardinal veins, albeit that the supracardinal veins, which form the azygos system, use the terminations of the cardinal veins to establish their eventual connections with the superior caval venous system.

Figure 23-9 The origin of the components of the definitive inferior caval vein. Note the relationship to the azygos venous system. These connections explain how the abdominal venous return can reach the superior caval veins when the inferior caval vein itself is interrupted.

The venous development discussed thus far has presumed the development of anastomotic channels and connection of the systemic venous sinus to the right-sided atrium. It is this process that produces the morphologically right atrium, which contains the entirety of the embryonic systemic venous sinus. The left side of the initial atrial component of the heart tube, together with the developing pulmonary veins, becomes the morphologically left atrium. Concomitant with these changes, the appendages balloon from each side of the atrial component of the heart tube. The appendage growing to the right assumes its typically triangular shape, incorporating the cephalic part of the valve of the systemic venous sinus to form the terminal crest and the spurious septum. The appendage growing from the pulmonary side is much narrower. It has no relation with the valves of the systemic venous sinus, and therefore lacks a terminal crest. All of this occurs concomitant with development of anastomoses from the left to the right side. Should the anastomoses develop in right-sided to left-sided fashion, then the left-sided atrium will incorporate the systemic venous sinus and become the morphologically right atrium, while the right-sided atrium becomes the morphologically left atrium. This will produce a mirror-imaged atrial arrangement.

In certain circumstances, however, the process of lateralisation does not occur, and the systemic venous tributaries retain their bilateral symmetry. This lack of lateralisation occurs in two forms. In the one, the valves of the systemic venous sinus are incorporated bilaterally, along with bilateral right atrial appendages. This process squeezes out the anlagen of the primary pulmonary vein so that there is either no atrial site, or else a restricted anomalous site, for pulmonary venous drainage. Such right isomerism is characterised by presence bilaterally of appendages with right morphology, bilateral sinus horns together with bilateral systemic venous drainage, as well as anomalous pulmonary venous drainage. In the other pattern, there is bilateral growth of morphologically left structures. Consequently, the pulmonary venous component predominates in relation to the systemic venous tributaries. The major systemic venous channels then make anomalous connections to the atrial chambers, which have morphologically left appendages bilaterally. The common cardinal veins are more successful in this respect, tending to enter the atrial roof on each side in absence of a terminal crest. The hepatic veins also enter the atrium directly, often bilaterally. The venous return from the lower body, in contrast, usually continues through the supracardinal azygos system, draining to one or other of the superior cardinal veins to produce azygos continuation of the inferior caval vein. In those cases with isomeric left appendages in which the inferior caval vein does achieve a direct atrial connection, it tends to do so separately from the hepatic veins. Because of these developmental associations, anomalous systemic and pulmonary venous connections are part and parcel of the syndromes of isomerism and visceral heterotaxy (see Chapter 22).

CLASSIFICATION OF SYSTEMIC VENOUS ANOMALIES

Even though the account of development given above provides the background to understand their morphology, an organised classification of the multiple anomalous systemic

Figure 23-10 The cartoon shows the course of a left superior caval vein (LSCV) in presence of a brachiocephalic vein. Compare with Figure 23-5.

venous connections can be most easily achieved by using anatomical subdivisions. Thus, we can consider aberrations of development in the superior and inferior caval veins and the coronary sinus, as well as totally anomalous systemic venous connection, and abnormal persistence of the embryonic valves of the systemic venous sinus. Prevalence, pathophysiology, clinical and laboratory findings, and management will be discussed where appropriate for each anomaly.

Anomalies of the Superior Caval Vein

A left-sided superior caval vein draining to the coronary sinus is the most common systemic venous anomaly. The venous channel, which follows the course of the

embryonic left cranial cardinal vein (see Fig. 23-5), enters the pericardial cavity to the left of the left upper pulmonary veins, and runs posterior to the dome of the left atrium, having the mouth of the left atrial appendage to its left side. The lesion has been noted in almost one in every 200 postmortems in the general population,⁴ but occurs in up to one-twentieth of patients with congenitally malformed hearts.⁵ The left-sided venous channel usually co-exists with a right-sided superior caval vein. A brachiocephalic vein connects these two structures in three-fifths of patients, with its size varying inversely with that of the left vein (Fig. 23-10). When present, the left vein usually is positioned anteriorly relative to both the aortic arch and the left pulmonary artery, but can pass posterior to these structures (Fig. 23-11). (See also Fig. 23-12.)

Although persistence of the left superior caval vein has no direct consequences concerning the mode of drainage of systemic venous return, its presence has recently been shown potentially to be of more concern. Thus, there is evidence that the persistent vein can impinge on the vestibule of the mitral valve, producing obstruction to left ventricular inflow which can be alleviated by surgical plication.⁶ There is also an increased incidence of left-sided obstructive lesions in patients with persistent left superior caval veins.⁷ Imaging of a left superior caval vein to the coronary sinus is usually achieved with cross sectional echocardiography (Fig. 23-13), but more recently magnetic resonance imaging is playing a greater role, particularly in older patients (Fig. 23-14).

Absent Right Superior Caval Vein

Complete absence of the right superior caval vein occurs occasionally in the presence of a left vein draining to the coronary sinus. In this situation, the left vein receives a right-sided brachiocephalic vein. A vestigial cord is often recognised as the remnant of the right superior caval vein when specimens are available for study.⁸

Left Superior Caval Vein with Interatrial Communication

Through the Mouth of the Coronary Sinus

The known spectrum of fenestration of the coronary sinus⁹ provides the understanding for an interatrial communication through the mouth of the coronary sinus.¹⁰ A localised window in the adjacent walls of the left atrium and coronary sinus produces a limited communication between the systemic venous channel and the left atrium

Figure 23-11 In this patient, the left superior caval vein runs beneath the aorta. As it passes inferiorly, it accepts the hemiazygos vein, descends medially into the inferior atrioventricular groove, and enters the right atrium through the enlarged mouth of the coronary sinus (Fig. 23-12). AO, aorta; LSCV, left superior caval vein; RA, right atrium; RSCV, right superior caval vein.

Figure 23-12 The heart is photographed from behind, showing the typical course of a persistent left superior caval vein, sandwiched between the left atrial appendage and the left pulmonary veins as it passes over the dome of the left atrium.

Figure 23-13 The left superior caval veins as seen by echocardiography. Note the absence of a bridging brachiocephalic vein. CS, coronary sinus; LSCV, left superior caval vein; PA, pulmonary artery; RA, right atrium.

Figure 23-14 The left superior caval vein draining to the coronary sinus as revealed by magnetic resonance imaging (arrow). CS, coronary sinus; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

(Fig. 23-15). When the deficiency is more marked, the left vein connects directly to the left atrium between the mouth of the left appendage and the site of drainage of the left pulmonary veins. In the total absence of the walls that usually separate the cavities of the coronary sinus and the left atrium, this leaves the enlarged mouth of the sinus to function as an interatrial communication (Figs. 23-16 and 23-17).

The clinical significance relates to whether the interatrial shunting is from right-to-left, or left-to-right. If there is an associated left superior caval vein, then there is an obligatory right-to-left shunt, with mild cyanosis. In the absence of a left superior caval vein, there may be a net left-to-right shunt. The presence of the persistent left-sided caval vein can be confirmed by injections of saline injection into a vein in the left arm, with subsequent opacification of the left atrium. In other cases, the fenestration can be seen with cross sectional imaging (see Fig. 23-17).

Left Superior Caval Vein Draining to the Left Atrium

When there is persistence of the left superior caval vein, the venous channel is reported to connect directly to the left atrium in just less than one-tenth of cases,¹¹ typically in the setting of complex malformations. Thus, bilateral superior caval veins, with the left vein draining to the left-sided

Figure 23-15 The heart is photographed from behind, showing two fenestrations between the cavity of the coronary sinus and the left atrium.

Figure 23-16 In this heart, all the walls that should normally separate the coronary sinus from the left atrium have disappeared, leaving the persistent left superior caval vein draining to the roof of the left atrium, and the mouth of the coronary sinus functioning as an interatrial communication. Note the intact oval fossa. LSCV, left superior caval vein.

atrium, are usually seen when there is isomerism of the atrial appendages. The so-called developmental complex¹² of left caval venous connection to the left atrium, with purported absence of the coronary sinus is, in reality, no more than absence of the walls normally interposed between the sinus and the left atrium (see Fig. 23-16). In this situation, it is the mouth of the coronary sinus that functions as the interatrial communication.¹¹ The left superior caval vein can also drain directly to the left atrium when there are no associated defects at atrial level, with either right-to-left shunting¹³ or left-to-right shunting.¹⁴

This anomaly can be seen by both cross sectional echocardiography and magnetic resonance imaging (Figs. 23-18 and 23-19). By echocardiography it is best seen in a sagittal long-axis view in the ductal cut (Fig. 23-20). Further exploration of the dome and posterior wall of the left atrium reveals absence of the walls that normally interpose between the persistent caval vein and the atrial cavity. The anomaly should be suspected when scanning a patient with an apparent abnormality of atrial arrangement. Magnetic resonance imaging is now being used more frequently to delineate the systemic and pulmonary venous drainage in those with isomeric atrial appendages.

Laevocardial Cardinal Vein

This channel,¹⁵ in reality, is neither laevo, atrial, or cardinal. It provides overflow to the systemic venous circuit when there is obstruction of the outlet from the left atrium and the atrial septum is intact or closed (Fig. 23-21). It typically runs a serpentine course (Fig. 23-22). It can also decompress the left side in situations such as divided left atrium (Fig. 23-23).

Right Superior Caval Vein Draining to the Left Atrium

Anomalous drainage of the right superior caval vein into the left atrium has been reported rarely as an isolated anomaly.¹⁶ We have never seen such a lesion in an autopsied specimen, albeit that we have recently been shown a good example revealed by three-dimensional echocardiography. Drainage of a right superior caval vein into both atriums is also described, being seen in a patient in whom the right-sided pulmonary veins drained into the superior caval vein, which then connected through separate channels into the two atriums.¹⁷ This seems more like a variant of the

Figure 23-17 In this patient, unroofing of the coronary sinus produces a small interatrial communication at the mouth of the coronary sinus (arrow). LV, left ventricle; RA, right atrium; RV, right ventricle.

Figure 23-18 The high sagittal cut demonstrates a left superior caval vein to the roof of the left atrium. Note the complete absence of the walls that usually separate the caval vein from the cavity of the left atrium. LA, left atrium; LSCV, left superior caval vein.

Figure 23-19 The magnetic resonance image shows a left superior caval vein draining to the roof of the left atrium (arrows). LV, left ventricle; RA, right atrium.

sinus venosus interatrial communication, albeit that other cases are reported in the foreign literature.

Aneurysm of the Superior Caval Vein

Parts of the superior caval vein may become aneurysmal as isolated abnormalities in asymptomatic patients. The term aneurysm is usually reserved for arterial structures, but has been applied to such discrete dilations of the superior caval vein, and is probably more appropriate than that of varix, which implies a twisted conformation. Most of the aneurysms have been described in adults, albeit that a recent report concerned a 13-year-old boy.¹⁸ It is presumed that these defects are of a congenital nature, and possibly reflect an inherent weakness in the structure of the venous wall. As far as we are aware, rupture of the aneurysms has yet to be reported.

Anomalies of the Inferior Caval Vein

Absence of the Hepatic Segment of the Inferior Caval Vein with Azygos Continuation

The most common venous anomaly involving the inferior caval vein is absence of its infrahepatic segment, with azygos continuation to the superior caval vein (Fig. 23-24).

Figure 23-21 The cartoon shows the course of the so-called laevoatrial cardinal vein. The anomalous channel arises from the roof of the left atrium that receives the pulmonary veins in normal fashion, so that it provides anomalous pulmonary venous drainage in the setting of normal pulmonary venous connections. The vein then runs a variable, often serpentine, course (Fig. 23-22) before terminating in the superior caval vein (SCV).

Figure 23-23 This patient had divided left atrium, with no orifice between the proximal and distal components of the left atrium, but with a decompressing laevoatrial cardinal vein indicated by the star. The upper left picture shows the connection with the brachiocephalic vein (asterisk), and the upper right panel shows the connection with the left atrium (arrow). Note the normal pulmonary venous drainage, as shown in the lower right panel. The lower left panel shows the divided left atrium. The left ventricle was not hypoplastic, as there was an associated perimembranous ventricular septal defect. IV, brachiocephalic vein; LA, left atrium; LACV, laevoatrial cardinal vein; LV, left ventricle; RA, right atrium.

Figure 23-22 The serpentine course of the laevoatrial cardinal vein (arrows). In essence a pulmonary to systemic venous collateral channel, it is typically found in the setting of hypoplasia of the left heart,¹⁵ but can exist in other settings. SCV, superior caval vein.

Figure 23-24 A heart-lung block photographed from behind. The venous return from the abdomen passes through a venous channel running posterior to the aorta, and terminating in the left superior caval vein. The abdominal inferior caval vein is interrupted, with only the hepatic veins draining directly to the atrium. This is interruption of the inferior caval vein with azygos continuation. This patient also had isomerism of the left atrial appendages.

Figure 23-25 The echocardiogram shows interruption of the inferior caval vein with azygos continuation to the right superior vena caval vein (RSCV). Note that the azygos continuation (arrow in right picture) runs in the paravertebral gutter behind the liver. AO, descending aorta; AV, azygos vein.

The dilated azygos system serves as the major channel of systemic venous return from the lower half of the body. Only the hepatic veins continue to drain to the right atrium, albeit also carrying the portal venous return. The lesion is the consequence of abnormal development of the right subcardinal system, which fails to anastomose with the right vitelline vein. The supracardinal venous system, which normally forms the azygos system, then provides continuation of systemic venous return to the developing superior caval vein.

The malformation is said to occur in 0.6% of all patients with congenital cardiac disease.¹⁹ When found, it should raise the suspicion of isomerism of the left atrial appendages, but certainly exists in patients with usual or mirror-imaged atrial arrangement.²⁰ In the setting of isomerism, the hepatic venous connections usually connect directly to the atriums, either separately or through a confluent channel. Strictly speaking, the anomalous vein in the setting of left isomerism is a hemiazygos vein, but it is convenient to term it the azygos vein. Interruption of the inferior caval vein is readily seen by cross sectional echocardiography, where the azygos vein is situated behind the liver in the paravertebral gutter. The thoracic connection with either the left or right superior caval vein can be seen in a high right or left sagittal plane (Fig. 23-25).

Inferior Caval Vein Connected to the Left Atrium

The inferior caval vein has been reported as connecting directly to the left atrium both with an intact atrial septum²¹ and in association with an atrial septal defect.²² In this respect, it is necessary to distinguish between direct connection to the left atrium and the arrangement in which an inferior caval vein overrides a low-lying interatrial communication and allows functional drainage of inferior caval venous flow to the left atrium. The latter situation can be exacerbated by persistence of an unduly prominent Eustachian valve that directs the flow into the left atrium (Fig. 23-26).

Miscellaneous Anomalies of the Inferior Caval Vein

A variety of minor abnormalities of the inferior caval vein have been documented in the general population. They have no definite relationship to other congenital cardiac lesions. These include duplication of the inferior caval vein below the level of the renal veins, left-sided inferior caval vein,

Figure 23-26 The cartoon shows a persistent Eustachian valve directing inferior venous caval flow into the left atrium. This should not be mistaken for connection of the inferior caval vein to the left atrium.

and circumaortic renal collar. The anomalies can easily be explained by variation in the pattern of regression and anastomosis of the many embryological structures that contribute to the development of the vein (see Figs. 23-6 through 23-9). They have no haemodynamic significance, but may be of importance when surgical procedures are necessary in the retroperitoneal area. The hepatic veins normally connect to the inferior caval vein, but have been reported to connect directly to the left atrium.²³ Complete absence of the inferior caval vein, with systemic venous return from the lower extremities flowing entirely through the paravertebral

Figure 23-27 The angiogram shows atresia of the mouth of the coronary sinus atresia (arrow) in the setting of a left superior caval vein (LSCV).

venous plexus and the azygos and hemiazygos systems, is also reported,²⁴ but was probably the consequence of venous thrombosis from a prior pelvic staphylococcal infection, with development of collateral channels.

Anomalies of the Coronary Sinus

Several systemic venous anomalies that involve alterations in normal structure of the coronary sinus have already been discussed. These include the various degrees of so-called

unroofing of the coronary sinus in association with a left superior caval vein connected directly to the left atrium. As we have discussed, this is better considered in terms of a spectrum of fenestration of the walls that usually separate the sinus from the cavity of the left atrium.^{9,10} Varying degrees of hypoplasia have also been reported, in which some of the cardiac veins drain separately through dilated Thebesian veins directly into the atriums. The Thebesian valve can also persist in its entirety, and produce atresia of the sinusal orifice (Fig. 23-27). This is also reported with coronary venous drainage to a persistent left caval vein. Intraoperative ligation of the caval vein in this setting produced coronary ischaemia and death.²⁵ Other rare anomalies include connection of the hepatic veins to the coronary sinus, fistulous communication with coronary arteries, and connection of the coronary sinus to the inferior caval vein. Diverticulums of the coronary sinus (Fig. 23-28) are also known to be associated with ventricular pre-excitation.²⁶ It is unusual for anomalies of the coronary sinus to occur as isolated defects. Any enlargement of this structure, therefore, should raise suspicions of an anomalous systemic or pulmonary venous channel draining through it.

Totally Anomalous Systemic Venous Connection

Various cases have been reported previously with alleged totally anomalous systemic venous connections.²⁷ The described anatomical features, however, are all suggestive of isomerism of the left atrial appendages.

Anomalies of the Embryonic Valves of the Systemic Venous Sinus

The valves of the systemic venous sinus are prominent structures during early embryological development, when the right valve nearly divides the right atrium into two portions. With normal maturation, they usually involute. As we have already described, the cephalic portion of the right

Figure 23-28 The coronary sinus, which drains a small left superior caval vein, is aneurysmal in a patient who had an associated ventricular septal defect. Note the dilated coronary sinus seen on the right-hand panel echocardiogram. CSD, dilated coronary sinus; LSCV, left superior caval vein; LV, left ventricle; RA, right atrium.

valve becomes incorporated into the terminal crest, while its caudal portion becomes the Eustachian and Thebesian valves. The left venous valve becomes incorporated into the atrial septum. The valves can persist in varied fashion, from small remnants to semilunar membranes with and without fenestrations. When seen in the form of fine or coarse fibrous strands extending across the cavity of the right atrium from the terminal crest to either the Thebesian or Eustachian valves the entity is known as a Chiari network. Such networks are usually not of haemodynamic significance, although Chiari himself attributed the death of his patient to embolisation of a thrombus formed on the network.²⁸ Undue persistence of the valves can produce partial or complete division of the right atrium into a venous component, accepting some or all of the systemic veins, and the remainder of the atrium, including the right atrial appendage and the vestibule of the tricuspid valve. The venous sinus is in communication with the oval foramen, which allows the potential for right-to-left shunting of systemic venous blood to the left atrium. In some instances, the dividing partition can balloon as a windsock membrane.²⁹ This can then extend through the tricuspid valve into the right ventricle. There is a striking association of pathological persistence of the right-sided venous valves with hypoplasia of the right ventricle and pulmonary arteries, probably because reduced flow through the tricuspid valve leads to failure of proper development of the right-sided cardiac structures. These lesions are discussed in greater detail in our chapter devoted to division of the atrial chambers (Chapter 26).

Pulmonary Venous Abnormalities

ANTHONY M. HLAVACEK, GIRISH S. SHIRALI, and ROBERT H. ANDERSON

In this chapter, we consider abnormalities of the pulmonary veins, in particular their anomalous connections to the systemic venous system. The variant of partially anomalous pulmonary venous connection associated with the sinus venosus interatrial communication is described in detail in the chapter that follows. The anomalous pulmonary venous connections so commonly associated with isomerism of the atrial appendages are mentioned in this chapter, but have been discussed more fully in Chapter 22, not least because of the particular problems of nomenclature that arise in the setting of isomerism. Though division of the morphologically left atrium was, in the past,¹ considered a pulmonary venous anomaly, we deal with this lesion, along with division of the morphologically right atrium, in Chapter 26.

TOTALLY ANOMALOUS PULMONARY VENOUS CONNECTION

Incidence and Aetiology

It was at the turn of the 17th century that Wilson² described a 'monstrous formation of the heart in which the superior caval vein was joined by a trunk formed by two large veins coming out of the lungs'. We now know that the various forms of such totally anomalous pulmonary venous connection, in the absence of isomerism of the atrial appendages, or visceral heterotaxy, accounted for one-fortieth of the patients registered in the New England Regional Infant Cardiac Program.³ As such, the entity ranked 12th in frequency, and occurred once in 17,000 live births. In the Baltimore–Washington Infant Study, the malformation was encountered less commonly, accounting for 1.5% of all patients with a cardiovascular malformation, and being seen once in 14,700 live births.⁴ Totally anomalous pulmonary venous connection is known to be part of the Holt–Oram, Klippel–Feil, phocomelia, and Schachermann syndromes.⁵ It is more difficult to establish the incidence of partially anomalous pulmonary venous connection, since anomalous connection of a solitary vein (Fig. 24-1) may be unrecognised either in life or death. Such anomalies have been reported in about 1 in 200 routine postmortems.^{6,7} Furthermore, in an extensive investigation based on surgical and autopsy experience, seven-tenths of all cases of anomalous pulmonary venous connection were found to be of the partial variety, albeit that this review included patients with isomerism of the atrial appendages.⁸

Earlier reports on totally anomalous pulmonary venous connection stressed the preponderance of males in the setting of infradiaphragmatic drainage,⁵ with an equal mix of gender in the remaining types. In those recorded

in the New England Regional Infant Cardiac Program,³ however, two-thirds with supracardiac and cardiac connections were males, while it was the infradiaphragmatic variant that showed an equal mix of genders. As with so many lesions, there are some examples of familial clustering,⁹ with one report¹⁰ suggesting autosomal dominant inheritance. Some evidence suggesting maternal exposure during the first 3 months of pregnancy to teratogens emerged from the Baltimore–Washington Infant Study.⁴ Reanalysis of that dataset in 2004¹¹ found the association with maternal exposures inconclusive, but identified a link between totally anomalous connection and paternal exposure to lead prior to conception.

Anatomy

Anomalous pulmonary connections take various forms, and show several important clinical features. The first important feature is the proportion of the pulmonary venous drainage that is connected to sites other than the morphologically left atrium. This can be a solitary pulmonary vein, all of the veins from one lung, or the entirety of the pulmonary venous drainage (Fig. 24-2). Combinations are also possible when all veins do not drain anomalously, so although rare, it can be possible for all of the drainage from one lung, and a solitary vein from the other lung, to

Figure 24-1 This picture shows anomalous connection of the right upper pulmonary vein to the superior caval vein (SCV). This was discovered as an incidental finding in an otherwise normal autopsy.

Figure 24-2 The cartoon shows the possibilities for anomalous connection of the pulmonary veins.

be connected to sites other than the morphologically left atrium. Once it has been established that a pulmonary vein, or pulmonary veins, are draining anomalously, it is equally important to determine the site of drainage, and whether all the veins drain to the same site. It is then necessary to seek stenotic areas or regions along the route of anomalous drainage. It is also necessary to establish whether the anomalous pulmonary venous connection is an isolated malformation, or part of a more complex anomaly, and whether there are associated structural malformations of the pulmonary vasculature.

Before discussing these important anatomic variables in more detail, we need to explain our use of the term anomalous pulmonary venous connection. This is because, in certain circumstances, pulmonary veins connected in normal fashion to the morphologically left atrium can drain anomalously to a systemic site, as for example when there is mitral atresia and an atrial septal defect, or fenestration to the coronary sinus, or in presence of the so-called laevoatrial cardinal vein (Fig. 24-3).

A pulmonary vein is connected anomalously only when it is attached to a site other than the morphologically left atrium. In this respect, it is also important to distinguish between the left-sided and the morphologically left atrium. In the presence of isomerism of the right atrial appendages, as we will show, all four pulmonary veins are frequently connected to the roof of an atrium with a morphologically right appendage, which can be left-sided. Because, in this setting, the atrium possesses a morphologically right appendage, this anatomical pattern is anomalous. Indeed, the pulmonary veins must be connected anomalously in the setting of right isomerism irrespective of their site of

Figure 24-3 The cartoon shows an example of totally anomalous pulmonary venous drainage in the setting of normally connected pulmonary veins, in this instance because a so-called laevoatrial cardinal vein joins the left atrium to the superior caval vein (SCV) with mitral atresia and an intact atrial septum.

drainage. The topic of pulmonary venous connections in hearts with isomeric appendages, therefore, represents a special situation. It is discussed in depth in Chapter 22. In this section, we are concerned primarily with totally anomalous connection in the setting of lateralised atrial chambers, in other words the usual and mirror-imaged arrangements, but we will make reference where appropriate to hearts with isomeric appendages.

When all the pulmonary veins are connected anomalously, then usually they drain to the same site. In some situations, nonetheless, different pulmonary veins are connected to separate anomalous sites. This is called mixed drainage. The sites of such drainage are the same as when the entirety of the pulmonary venous return reaches an extracardiac site through a confluence. These sites of anomalous connection are divided into supracardiac, cardiac, and infracardiac groups. The first two, taken together, constitute supradiaphragmatic drainage, while infracardiac drainage is at the same time infradiaphragmatic (Fig. 24-4).

Cardiac and intracardiac anomalous connections account for approximately one-quarter each of the total group. Supracardiac connection can be to the left brachiocephalic vein, directly to the right superior caval vein, to the azygos system of veins, or to the left superior caval vein, albeit that when the left vein drains to the coronary sinus this is considered cardiac drainage. In the most common pattern, the four pulmonary veins usually join in turn to a venous channel behind the left atrium. This channel is traditionally termed the confluence but the individual veins usually join the channel sequentially. From this horizontal channel, a vertical vein typically runs through the left paravertebral gutter to join the left brachiocephalic vein, which

Figure 24-4 The cartoon shows the different sites of anomalous pulmonary venous connection. The commonest site for anomalous connection is supracardiac, accounting for nearly half of cases.

then terminates in the right superior caval vein (Fig. 24-5). It is the course of the vertical vein that usually determines whether or not the pathway is obstructed. If the vein passes anterior to the left pulmonary artery, then this course is not associated with obstruction. Should the vein pass between the left pulmonary artery and the left bronchus, these two structures clasp the channel in the so-called bronchopulmonary vice (Fig. 24-6). Obstruction with this snowman pattern of anomalous connection can also occur, albeit rarely, at the opening of the brachiocephalic vein into the superior caval vein. Supracardiac connection can also be found when the vertical vein joins directly with the right superior caval vein. Obstruction may then occur either at this caval venous junction, or in another vice, this time between the right pulmonary artery and the carina. When the anomalous pulmonary veins join the systemic venous system through the azygos vein, the horizontal vein usually crosses from left to right beneath the heart, again receiving the individual pulmonary veins in sequential fashion. The vertical vein then ascends in the right paravertebral gutter, joining the superior caval vein through the azygos vein (Fig. 24-7).

When there is usual, or mirror-imaged, atrial arrangement, then almost always the cardiac form of anomalous connection is found when the pulmonary veins join the right atrium via the coronary sinus (Fig. 24-8). It can be questioned whether this should be considered a cardiac connection, or one via the persistent left superior caval vein. Irrespective of such niceties, there is no question but that the site of return is within the heart, so cardiac connection is an apt description. The individual pulmonary veins can drain in various patterns to the coronary sinus, but the

Figure 24-5 The picture shows the typical snowman pattern of supracardiac totally anomalous pulmonary venous connection to the superior caval vein (SCV). The anomalous venous pathway forms the head of the snowman, whilst the ventricular mass accounts for the body. The arrow shows the direction of flow of the anomalous pulmonary venous return through the brachiocephalic vein.

Figure 24-6 The cartoon shows the nature of the bronchopulmonary vice, which produces obstruction with supracardiac connections.

final common pathway is the sinus within the left atrio-ventricular groove, this typically being enlarged relative to the normal situation. Separate walls of coronary sinus and left atrium then separate the horizontal venous channel from the left atrial cavity, albeit that the walls can readily be removed surgically. Repair of the anomalous connection is then achieved simply by closing both the mouth of the coronary sinus and the interatrial communication,¹² taking care, of course, to respect the atrioventricular conduction

Figure 24-7 In this specimen, from a patient with isomeric right atrial appendages, the horizontal vein passes from left to right and ascends in the right paravertebral gutter, draining in supracardiac fashion through the azygos vein.

Figure 24-9 In this heart from a patient with isomeric right atrial appendages, all the pulmonary veins drain through a midline fibrous confluence.

Figure 24-8 The picture shows totally anomalous pulmonary venous connection through the coronary sinus to the left atrium. The heart is photographed from behind and from the left side. If the walls separating the cavity of the sinus from the left atrium are removed, the anomaly can be corrected simply by closing the right atrial mouth of the coronary sinus.

Figure 24-10 This heart is again from a patient with isomeric right atrial appendages. Note the absence of the coronary sinus. All pulmonary veins connect directly but separately to the right-sided atrium, as shown by the arrows.

tissues within the triangle of Koch. Obstruction is rare when the pulmonary veins drain through the coronary sinus, but can be produced by persistence of the Thebesian valve, or within the sinus when the individual veins connect in unusual fashion.

Direct connection of the pulmonary veins to the morphologically right atrium is exceedingly rare other than in the setting of isomerism of the right atrial appendages. In this setting, the coronary sinus is absent, and most usually the atrial septum is deficient, frequently virtually absent. The pulmonary veins then tend to crowd together, opening through a midline fibrous confluence in the atrial roof (Fig. 24-9). Because the confluence lacks muscle,¹³ it can be obstructive. Less frequently in hearts with isomeric right appendages, the atrial septum can be much better formed, yet still the pulmonary veins connect directly to one of the atriums (Fig. 24-10). This arrangement must be anticipated

in hearts with usual or mirror-imaged atrial arrangement, but we have yet to identify such a case.

The final site of anomalous connection is both infracardiac and infradiaphragmatic. In this pattern, the pulmonary veins join together, entering a descending vertical vein that passes into the abdomen through the oesophageal orifice of the diaphragm. It then usually drains to the portal vein, or to one of its tributaries (Fig. 24-11). Drainage to the inferior caval vein is very rare. When the infracardiac connection is to the portal venous system, obstruction is almost always present subsequent to closure of the venous duct. Once this component of the fetal circulation has closed, the blood must pass through the hepatic tissues to reach the systemic veins. Additional discrete stenosis can be found as the vertical vein passes through the diaphragm, while the channel can also break up into a delta of smaller channels that terminate in the tributaries of the portal vein.

Figure 24-11 The picture shows infradiaphragmatic and infracardiac totally anomalous pulmonary venous connection. Having passed into the abdomen, the venous confluence terminates in the portal venous system.

In all the situations illustrated thus, we have shown the anomalously connecting pulmonary veins draining to the same site within the systemic system. As discussed, it is also possible for different veins to terminate in different anomalous sites. This is called mixed anomalous connection.¹⁴ When seen, some of the veins can join together before draining to one of the multiple sites of anomalous connection, but different parts of the lung usually drain through discrete channels. In very rare situations, all of the pulmonary veins can join a common confluence, but the confluence itself then drains via separate channels, for example to both a left vertical vein and the coronary sinus.¹⁴ With all these patterns of mixed anomalous connection, the same potentials exist for the pathways to become obstructed as when all the pulmonary veins drain anomalously to the same site, as discussed above.

Even excluding those cases of totally anomalous pulmonary venous connection associated with isomeric right atrial appendages, a large proportion of the patients have significant associated malformations. In these patients, such as those with abnormal ventriculo-arterial connections or tetralogy of Fallot, the associated abnormality is probably the major lesion. Even when the anomalous connection is isolated, there is almost always an interatrial communication present, so that venous blood is able to reach the left side of the heart. The atrial septum, nonetheless, can be intact. This then requires an alternative route for blood to reach the left side of the heart.

In any patient with totally anomalous pulmonary venous connection, the size of the left atrium and left ventricle are of obvious concern to the surgeon. At first sight, these structures seem small to the morphologist because of the disparate hyperplasia of the right atrium and right ventricle. Measurements, however, show that the left-sided structures are usually of adequate dimensions.¹⁵ It is rare for there to be any great distance between the pulmonary venous confluence and the left atrium (see Fig. 24-11). Taken together, these features serve to facilitate surgical repair in virtually all patients. Problems, when they exist,

are likely to be found in patients with mixed drainage, or in the setting of isomerism of the morphologically right atrial appendages.

Further problems can be created by changes in the pulmonary vasculature. Autopsy studies reveal changes in the veins of all patients studied, even including those dying on the first day of age, indicating that the changes themselves occur during fetal life. The veins take on arterial characteristics, while there is also an increase with age in the muscularity of the pulmonary arteries.¹⁵⁻¹⁷ All these features point to the need for immediate surgical repair once the anomaly is diagnosed.

Morphogenesis

Knowledge of development of the pulmonary veins provides a good explanation for anomalous pulmonary venous connections. The developing atrium is itself initially connected to the mediastinum through the so-called dorsal mesocardium, even prior to formation of the lung buds from the trachea (see Chapter 3). As the lungs develop, the plexus of intrapulmonary veins joins with a pulmonary venous channel that canalises in the developing mediastinum. The newly formed primary pulmonary vein then uses the original connections of the dorsal mesocardium to gain access with the atrial component of the developing heart tube.^{18,19} After normal fusion with the developing intrapulmonary venous plexuses, the pulmonary veins themselves are cannibalised by the atrium to form the venous components of the normal morphologically left atrium.¹⁹ This occurs relatively late in development. Totally anomalous pulmonary venous connection is the consequence of failure of canalisation of the pulmonary venous channel in the mediastinum. Initially, since the lung buds themselves are derived from the foregut, the intrapulmonary veins also have connections to the systemic venous system.²⁰ Should the pulmonary venous channel fail to develop, these anastomoses between pulmonary and systemic venous systems persist and enlarge. An anastomosis with the anterior cardinal systemic venous system then results in supracardiac anomalous connection. Anastomosis with the systemic venous sinus, or the left sinus horn, produces cardiac connection, while infradiaphragmatic connection is the consequence of anastomosis with the omphalomesenteric system. In the strictest sense, these anastomoses are neither anomalous nor pulmonary.²¹ If they persist, nonetheless, they certainly result in an anomalous pulmonary venous connection. Rarely, hearts may be found in which the pulmonary venous channel has formed, but has become atretic in its course between the atrium and the intrapulmonary venous plexuses.²² Indeed, sometimes the pulmonary veins may be adjacent to the left atrium, but with musculature present between the two developmental components. An anomalous channel, analogous to the laevoatrial cardinal vein, then provides the only route for drainage of pulmonary venous blood. All of these examples, nonetheless, are readily explained using the developmental hypothesis discussed above. It should be noted that while the development of normal pulmonary venous anatomy is well studied, current thoughts about the development of anomalous pulmonary venous connections is conjectural, based on a combination of

morphological observations and findings from normal development. The above discussion should, therefore, be viewed in light of that caveat.

Pathophysiology

Shunts

There is an obligatory left-to-right shunt, since pulmonary venous return is to the systemic veins or right atrium. A systemic output can only be maintained if there is a right-to-left shunt, which is almost always at atrial level. As discussed above, exceptional cases have been described in which the atrial septum was intact. In these patients, the right-to-left shunt occurred either at ventricular^{21,23} or ductal level.²⁴

When the right-to-left shunt is at atrial level, there is a tendency for fetal patterns of flow to be maintained by the valvar mechanism of the oval foramen.^{5,25} Thus, in most patients with infradiaphragmatic connection, the oxygenated blood ascending the inferior caval vein towards the right atrium is directed towards the left atrium. Systemic arterial oxygen saturation is accordingly higher than that in the pulmonary arteries. When the anomalous venous connection is supracardiac, oxygenated blood tends to be directed down the superior caval vein and through the tricuspid valve. Consequently, in some of these patients, pulmonary arterial blood is more oxygenated than systemic arterial blood. In the others, mixing is complete. Similar patterns are found for anomalous connection to the coronary sinus. This is presumably because the orifice of the coronary sinus is directed more towards the tricuspid valve than the oval fossa.^{5,26}

Obstruction to Pulmonary Venous Return

Obstruction to pulmonary venous return can occur at any of the anatomical sites documented above. Infants with evidence for borderline venous obstruction should be reevaluated, since the combination of decreasing pulmonary vascular resistance and increased flow of blood to the lungs typically seen in the postnatal period may unmask more severe obstruction.²⁷ When there is definable obstruction, the right ventricular pressure is usually suprasystemic.^{28,29} There are many infants, particularly those with return to the coronary sinus, in whom the systolic pressure in the two ventricles is more or less equal, despite absence of any definable obstruction.²⁸ Indeed, in one study, no significant difference was found in systolic pressures measured in either the right ventricle or pulmonary arteries between patients with and without obstruction, and with supracardiac or intracardiac connections.²⁶ This suggests that the main cause of pulmonary hypertension in patients without apparent pulmonary venous obstruction is elevation of pulmonary resistance, presumably as a result of extension of muscle into peripheral arterioles and veins.^{15,16} If this is the cause, the almost invariable fall to normal after successful repair indicates that the process is reversible. Alternatively, at least part of the problem may result from undetected anatomical causes of pulmonary venous obstruction.³⁰

The contribution of the oval foramen to the problem is controversial. In theory, obstruction of this foramen leads to a high right atrial pressure, which impedes pulmonary venous return, thus producing pulmonary hypertension. Gathman and Nadas⁵ argued on three grounds, however,

that significant obstruction of pulmonary venous return at atrial level was rare. First, patients as a group had similar right atrial pressures whether they were pulmonary hypertensive or not. Second, about a third of patients with pulmonary hypertension had no pressure gradient at atrial level. Indeed, in a few, mean left atrial pressure was higher than right. Third, almost all patients with pulmonary vascular obstruction also had pulmonary venous obstruction. While these arguments are persuasive as to the insignificant role of the oval foramen in producing pulmonary hypertension, they do not rule out the possibility that a small foramen could limit systemic flow.

Consequences of Pulmonary Venous Obstruction

When pulmonary venous return is unobstructed, right ventricular diastolic pressure is low and right ventricular compliance relatively high. Blood returning to the right atrium, therefore, tends to enter the right ventricle rather than the left atrium. Flow of blood to the lungs tends greatly to exceed flow in the systemic circuit. Right ventricular end-diastolic and stroke volumes are considerably increased in consequence.^{31,32} Since mixing of pulmonary and systemic venous blood is complete, apart from the minor degrees of streaming discussed above, right atrial and, therefore, systemic arterial blood is well oxygenated, with saturations of oxygen found in excess of 90%.

In the presence of pulmonary venous obstruction, in contrast, pulmonary venous pressure is raised. Pulmonary oedema is then produced if the pressure is sufficiently severe, though bronchopulmonary venous anastomoses may relieve pressure to some degree. In severe cases, nonetheless, pulmonary arterial pressure is raised even above systemic pressure, and pulmonary blood flow is reduced. The right ventricle, therefore, becomes pressure rather than volume overloaded.^{31,32} Systemic arterial oxygen saturation may then fall to values of 20% to 30%. The depression of systemic arterial saturation, and possibly also output, results in tissue hypoxemia and metabolic acidosis. These effects of pulmonary venous obstruction are compounded by the changes in small pulmonary veins and arteries already described, which may further increase pulmonary vascular resistance.

In the occasional patient who survives infancy without severe pulmonary venous obstruction, late pulmonary vascular obstructive disease may develop as in those with atrial septal defect. The effects are the same as those of pulmonary venous obstruction, except that no pulmonary oedema occurs.

Presentation and Symptoms

Very occasionally, totally anomalous pulmonary venous connection can present as sudden death in the first 2 months of life.³³ As long ago as 1962, Hastreiter and colleagues²⁴ recognised that the main determinant of the clinical picture was the presence of pulmonary venous obstruction. Consequently, for each of the ensuing sections relating to the clinical picture, patients will be divided into those with and without pulmonary venous obstruction. Some patients with only modest obstruction fall between the two groups and exhibit features of both.

Patients with severe pulmonary venous obstruction present in the first week or two of life with obvious cyanosis and difficulties with feeding and respiration.³⁴

In contrast to what is observed in the respiratory distress syndrome, grunting respiration is very rarely seen in obstructed venous return. Pointers to respiratory distress syndrome rather than totally anomalous pulmonary connection are maternal diabetes, prematurity, caesarean section, and very early onset of respiratory difficulties. Any, or all, of these can, nonetheless, be found in the setting of anomalous pulmonary venous connection. In the registry of the Extracorporeal Life Support Society, containing 4823 patients, 623 patients were thought to have persistent fetal circulation. Of these, one-tenth were shown to have congenital heart disease. About half had totally anomalous pulmonary venous connection, while one-tenth had complete transposition. This emphasises how easy it is to mistake totally anomalous pulmonary venous connection for persistent fetal circulation if echocardiography is not performed.³⁵ A unique mode of presentation, haematemesis, was described in one patient with infradiaphragmatic return to the left gastric vein.³⁶ Another unique mode was severe unconjugated hyperbilirubinemia in the setting of infradiaphragmatic return. The patient survived exchange transfusion and surgical repair.³⁷

Patients without severe pulmonary venous obstruction tend to present in heart failure at 2 to 3 months of age. They have a history of difficulties with feeding and, sometimes, chest infections. Cyanosis is generally not a symptom.

Those with severe pulmonary venous obstruction are sick neonates with obvious or severe cyanosis. Skin mottling is frequent, reflecting poor peripheral perfusion and metabolic acidosis. Tachypnea is usually marked, though respiration is quiet. Hepatomegaly is occasionally considerable, particularly when drainage is to the portal vein. The peripheral pulses are often somewhat weak. The precordium is quiet. On auscultation there are usually no murmurs. If a murmur does exist, it is usually unimpressive and mid-systolic. Occasionally a venous hum is heard in the region where pulmonary venous return is obstructed, under the left clavicle, for example, in anomalous connection via a left vertical vein. The first heart sound is single and the second heart sound is described as exhibiting physiological or fixed splitting.⁵ The pulmonary component is accentuated and a fourth heart sound may be heard. Rarely, the second heart sound appears single.

When seen from the end of the bed, patients without severe pulmonary venous obstruction resemble patients with large ventricular septal defect. They are scrawny and tachypneic, with retractions. The presence of cyanosis can certainly be missed if the infant is examined in a poor light. Even in a good light, it may not be detected. There is usually hepatomegaly, and rales may well be heard in the lungs.

The peripheral pulses are normal to small and the precordium overactive, but without any thrill. On auscultation, the first heart sound is normal and, usually, there is wide fixed splitting of the second sound. An ejection systolic murmur is heard in the pulmonary area owing to excessive flow through the pulmonary valve. A mid-diastolic murmur tends to be heard at the lower left sternal border, representing excessive flow through the tricuspid valve.

Patients without pulmonary venous obstruction very occasionally survive infancy without heart disease being detected. These patients present as does a typical patient with atrial septal defect, but with the added features of mild cyanosis and clubbing.

Figure 24-12 This chest radiograph is typical of obstructed totally anomalous pulmonary venous connection, showing a ground-glass appearance in both lung fields and a small cardiac shadow.

Investigations

Chest Radiography

Newborns with severe pulmonary venous obstruction have an extremely characteristic chest radiograph, with a small or normally sized heart framed by ground-glass lung fields^{24,38,39} (Fig. 24-12). Kerley B lines are occasionally seen.⁴⁰ These appearances are sometimes confused with those of respiratory distress syndrome. The latter diagnosis can easily and correctly be made in most cases in which it is present because of the more patchy distribution of changes in the lung fields. Furthermore, obliteration of part or the entire cardiac silhouette and the appearance of an air bronchogram are both highly characteristic of respiratory distress syndrome and are rare in those patients with totally anomalous pulmonary venous connection.

Patients without severe pulmonary venous obstruction have enlarged hearts because of the right ventricular volume overload, together with engorged lung fields. The pulmonary trunk becomes prominent in older patients, as does the left vertical vein when this is the site of the anomalous venous connection. This gives rise to the snowman appearance, known to almost every paediatrician and also described as the W. C. Fields heart. This is now of mainly historical importance because patients usually have their defect corrected long before the snowman has time to appear, which was usually in the second year of life.⁴¹ Less than one-third of infants with supracardiac anomalous connection exhibit the snowman.²⁸ Exceptionally, however, the snowman has been seen at 3 months of age.⁵

Electrocardiography

The electrocardiogram shows right-axis deviation with a clockwise frontal plane loop and right ventricular hypertrophy. V_1 usually shows an rsR' pattern, though a qR is seen in four-fifths of patients. The latter might be thought to indicate the presence of more severe pulmonary hypertension, but there is poor correlation between the two.⁵ Disturbances of conduction are rare. Under 1 month of age, only about one-twelfth of patients have right atrial hypertrophy, whereas this is seen in three-quarters between 1 and 3 months, and in nine-tenths over 3 months. Patients with pulmonary venous obstruction, who present younger,

are much less likely to have right atrial hypertrophy than those without pulmonary venous obstruction.

Echocardiography

Echocardiography is the definitive non-invasive method of diagnosis. Even as long ago as 1979, it was shown that it was possible to image at least one vein connected to the left atrium in 94% of infants under 3 months of age with normally connected pulmonary veins, and at least two in 77%.⁴² Correlative anatomical studies suggest that the subcostal and apical approaches image the normal left lower and right upper pulmonary veins, while the suprasternal approach, given a good window, can demonstrate all four. With modern techniques, therefore, it should be possible to demonstrate positively the normal pulmonary venous connections in all neonates and infants. Any infant in whom normal pulmonary venous connections cannot be clearly seen should be sent for further imaging, whether it is additional echocardiography or other modalities.

When performing an echocardiogram, there are certain clues which should direct one towards the diagnosis of totally anomalous pulmonary venous connection. Exclusive right-to-left shunting at the atrial level through an atrial septal defect or patent oval foramen is abnormal in any setting, and should not be presumed to be a result of right ventricular hypertension. It should be assumed that any patient with this finding has totally anomalous pulmonary venous connection until proven otherwise. Other clues include a small left atrium, a dilated superior caval vein (Fig. 24-13), non-pulsatile caudally-directed flow seen below the level of the heart in subcostal imaging, or non-pulsatile cranially-directed flow seen above the level of the heart. Each of these findings should lead one to entertain the possibility of totally anomalous pulmonary venous connection.

Failure to demonstrate any pulmonary vein connected to the left atrium should lead to an assiduous search for the key positive feature required for diagnosis. This is the pulmonary venous confluence, or collecting venous channel, which was recognised in 21 out of 23 patients studied by Smallhorn and colleagues.⁴³ As has been emphasised, when the pulmonary veins are connected anomalously to

Figure 24-13 In this image, taken from the subcostal long-axis view angled posteriorly, note the severely dilated superior caval vein (SCV) emptying into the right atrium (RA), suggesting the presence of anomalous pulmonary venous connection. Further investigation revealed a confluence (C) behind the left atrium, leading to a vertical vein (VV), which connected to the left brachiocephalic vein (BCV). L, left; S, superior.

Figure 24-14 In most cases of totally anomalous pulmonary venous connection, echocardiography reveals an echo-free non-pulsatile region beyond and clearly separate from the left atrium. In this image, taken from the subcostal long-axis view, the pulmonary venous confluence (C) can be seen posterior and superior to the left atrium (LA). Colour Doppler can be applied to this view, clearly distinguishing this vessel from a pulmonary artery. L, left; RA, right atrium; S, superior.

the coronary sinus, the collecting venous channel is the coronary sinus itself. From multiple views, the confluence can be seen as an echo-free non-pulsatile region posterior and clearly separate from the left atrium (Fig. 24-14). Care should be taken to distinguish this confluence from a pulmonary artery. The pulmonary arteries originate from the pulmonary trunk, are more anterior, and are usually pulsatile. The subcostal and parasternal short-axis views also demonstrate the size of the interatrial communication. A characteristic picture of the confluence is obtained in the suprasternal or parasternal short-axis views, in which the four converging pulmonary veins can appear in the form of a cross⁴³ (Fig. 24-15). The vertical vein can be readily identified from the suprasternal approach (Fig. 24-16). The confluence can also be a longer channel, collecting the individual veins sequentially, and, even more rarely, may

Figure 24-15 Suprasternal view of totally anomalous pulmonary venous connection. The appearance of the right pulmonary veins (RUPV, RMPV, and RLPV) entering into the confluence (C), along with the left lower pulmonary vein (LLPV) creates a cruciate appearance. This image, however, can mimic the normal appearance. Therefore, it is important to follow the course of the confluence (as is done in Fig. 24-20) A, anterior; L, left; RPA, right pulmonary artery.

Figure 24-16 This suprasternal view, angled to the left, shows the left lower pulmonary vein (LLPV) draining into a confluence (C), which then drains into a superiorly-directed vertical vein (VV). L, left; S, superior.

Figure 24-18 In this apical view, rotated clockwise and angled posteriorly, the pulmonary venous confluence (C) is seen leading to a superiorly directed vertical vein (VV). Note that colour Doppler clearly distinguishes this vessel from a left superior caval vein, which would have flow directed towards the transducer. L, left; LA, left atrium; S, superior.

be somewhat removed from the left atrium. Once the confluence has been discovered, its connection to the systemic venous circulation must be determined.

A descending vein, as found in anomalous infradiaphragmatic connection, can sometimes be seen descending from the confluence from the suprasternal approach. Much more commonly, the descending vein is found by placing the transducer so as to obtain a subcostal long-axis cut of the aorta or inferior caval vein and then scanning from left to right.^{43,44} The descending vein is recognised as it penetrates the diaphragm. It is distinguished from the aorta both by its lack of pulsation and its lack of connection to the superior mesenteric artery. It is differentiated from the inferior caval and hepatic veins by its failure to enter one or other atrium and by the fact that it originates behind the heart, where branching can sometimes be recognised (Fig. 24-17). If the site of termination is the portal vein, the descending vein often appears as a finger

Figure 24-17 In this subcostal short-axis image, a large, posteriorly-directed vertical vein (VV) is seen. This vessel connects with the portal system inferior to the screen. Turbulence is seen in the region of the venous duct (arrow), representing obstruction to pulmonary venous return (see Fig. 24-22). P, posterior; RA, right atrium; S, superior.

pointing anteriorly from the oesophageal hiatus towards the hepatic portal. These discriminating features are sufficient in our experience to be diagnostic. If doubt persists, then the inferior caval vein can be distinguished from a descending pulmonary vein by its opacification following injection of microbubbles into a leg vein.⁴⁵ Alternatively, pulsed Doppler ultrasound or colour Doppler can be used to show that the descending pulmonary vein contains non-pulsatile blood moving inferiorly, while the inferior caval vein contains blood moving superiorly.⁴⁶

A left vertical vein is best seen from the suprasternal approach, in which its connection with the brachiocephalic vein is easily visualised. The vertical vein can usually be traced from the confluence, particularly since its initial upward course and the confluence can often be seen in subcostal and apical cuts (Fig. 24-18). If questions remain, then Doppler interrogation or injection of contrast bubbles into the left arm will demonstrate the direction of flow in the vertical vein. Similar rules apply when the vertical vein ascends in the right paravertebral gutter and terminates in the azygos vein.

If neither an ascending nor descending vein is identified, then the anomalous connection is most likely either to the coronary sinus or directly to the right atrium. If it is to the coronary sinus, then that structure, best identified in cross-sections in a parasternal long-axis cut or the apical four-chamber cut as it lies within the left atrioventricular groove, will be enlarged and will bulge anterosuperiorly into the left atrium. Great care must be taken to distinguish between enlargement of the coronary sinus owing to persistence of the left superior caval vein and the pattern in which the pulmonary veins drain into it. Colour Doppler can be used to identify pulmonary veins draining into the sinus (Figs. 24-19 and 24-20). The inferior margin of the coronary sinus thus imaged corresponds to the atrioventricular junction. If the superior margin lies more or less parallel to it, this suggests connection to a left superior caval vein. If, however, the superior margin bulges superiorly, then anomalous pulmonary venous connection

Figure 24-19 In this patient with totally anomalous pulmonary connection, a suprasternal view reveals three pulmonary veins (RUPV, RLPV, and LLPV) draining into the coronary sinus posterior to the left atrium (LA). Further imaging revealed that the left pulmonary vein drained into a separate vertical vein (see Fig. 24-30), emphasising the importance of identifying all four pulmonary venous connections. C, confluence; L, left; P, posterior.

Figure 24-20 This apical four-chamber view reveals drainage of the left lower pulmonary vein (LLPV) into the coronary sinus (CS). L, left; LA, left atrium; RA, right atrium; S, superior.

should be suspected. This distinction can be confirmed by making small tilting and rotational movements of the transducer, which show the anomalously connecting pulmonary veins. Anomalous connection to the right atrium can be diagnosed if there is no ascending or descending vein, the coronary sinus is of normal size and the pulmonary veins can be followed to their site of entry to the right atrium. The echocardiographer should consider measuring the diameter of all four pulmonary veins between hilum and confluence, as the sum of these diameters is a strong and independent predictor of surgical survival.⁴⁷ Most of the late deaths in this study were the result of individual pulmonary venous stenosis at sites remote from the surgical

Figure 24-21 This image, taken from a suprasternal view, shows a stenotic vertical vein (VV) connecting to the left brachiocephalic vein (BCV) in a patient with obstructed supracardiac totally anomalous pulmonary venous connection. Note the aliased flow in the vertical vein. P, posterior; S, superior.

anastomosis to the left atrium. In older patients, it can be difficult to image pulmonary veins from the precordium. Under these circumstances, transoesophageal echocardiography can be most helpful.⁴⁸

Colour Doppler is essential to diagnosis in these patients. First, it becomes impossible to confuse a left vertical vein draining to the brachiocephalic vein with a persistent left superior caval vein, except in the highly improbable association with atresia of the coronary sinus. The differences demonstrated in direction of flow apply equally to distinction between the inferior caval vein and the descending pulmonary venous pathway. Second, where there is doubt as to whether an image obtained is a genuine pulmonary vein or an artifact, the demonstration of colour within the structure indicates that it is vascular. Third, sites of obstruction along the pulmonary venous pathway can be demonstrated as points of turbulence (Fig. 24-21), or even absent flow, both pre- and post-operatively.⁴⁹⁻⁵¹ As is essential with colour Doppler imaging of any venous structure, care must be taken to ensure an appropriate Nyquist limit for optimal detection of pulmonary venous drainage and obstruction.

In areas where colour Doppler suggests obstruction, pulsed wave Doppler offers an objective measure. The presence of a focal increase in flow velocity with a continuous, non-phasic flow pattern distally is a characteristic finding²⁷ (Fig. 24-22). A sensitivity of 100% and specificity of 85% have been claimed for detection of obstruction by cross-sectional imaging and colour Doppler.⁵²

It is now standard of care to diagnose and repair totally anomalous pulmonary venous connection based on echocardiography alone. In 1983, Stark and colleagues⁵³ first reported successful repair of totally anomalous pulmonary venous connection in six young infants without previous cardiac catheterisation. Subsequent experience confirms that skilled use of cross sectional echocardiography avoids the need for cardiac catheterisation in the majority of patients.⁵⁴ Mixed totally anomalous pulmonary venous return cannot always be recognised,^{54,55} but then such arrangements are not always diagnosed by traditional angiography. As always, if the clinical and cross sectional echocardiographic findings do not fit the clinical situation, additional imaging should be performed without hesitation.

Figure 24-22 The Doppler profile that corresponds with the image in Figure 24-17. It reveals high velocity flow with a continuous, non-phasic flow pattern, which is characteristic of obstructed pulmonary venous flow.

Ultrasound technology has progressed to a degree that it is possible to diagnose totally anomalous pulmonary venous connection by fetal echocardiography, although it is often missed on screening ultrasounds in the absence of additional cardiac anomalies. The presence of a confluence behind the left atrium, a vertical vein, or a widened gap between the descending aorta and the posterior wall of the left atrium are the most consistent echocardiographic clues.^{56,57} As with postnatal echocardiography, colour and spectral Doppler analysis can assist greatly in identifying venous obstruction.

Cardiac Catheterisation

Cardiac catheterisation is rarely indicated in this era. If performed, it will document the pathophysiology already indicated. The pulmonary venous anatomy can almost always be delineated non-invasively, and the clinical scenario of pulmonary venous obstruction can almost always be determined without invasive testing.^{27,52} If performing catheterisation, it should be remembered that passage of a catheter across an obstruction will temporarily make it worse. Since obtaining the information demands advancing the catheter through an abnormally positioned vein, the safest approach is first to determine the site of the vein. This can be done using echocardiography, computed tomographic angiography, or magnetic resonance imaging. Vertical veins can be entered with ease using a suitably curved catheter. If necessary, a guide wire can be used, passing the catheter from below through the right atrium and via the right superior caval and brachiocephalic veins.²⁸ When return is to the coronary sinus, this structure may be entered in the usual fashion. Having reached the coronary sinus, it is extremely important to try and enter all pulmonary veins, in order to detect any pressure differences between pulmonary veins or confluence and coronary sinus, or else between coronary sinus and right atrium. It is usually a simple matter to enter the pulmonary confluence when it connects either to the right atrium or to the right superior or inferior caval veins. In the special case of anomalous connection to the portal vein, the umbilical vein is the approach of choice.⁵⁸ No-one has reported success in traversing the venous duct from the inferior caval

vein. In any case, this structure has often closed by the time the patient is catheterised. The catheter should not be left in position for long, as pulmonary venous pressure can rise as high as 50 mm Hg if it is not removed at once.⁵⁹

Traditional Angiography

It is not easy to demonstrate well the detailed anatomy of the route of anomalous return by traditional angiography. This is probably why relatively little was published on the subject. In theory, selective pulmonary venous injection is the method of choice. In practice, it is often a frustrating experience because of the refusal of contrast medium to reflux into pulmonary veins against the current unless there is severe pulmonary venous obstruction. The pulmonary venous injection in obstructed connection to the portal vein published by Tynan and colleagues⁵⁸ shows superb opacification of the pulmonary veins. In contrast, on injection into the coronary sinus, it is rare to see opacification of pulmonary veins even if all are connected to it. While the techniques below generally allow one to define the pulmonary venous anatomy, these findings can almost always be defined non-invasively using echocardiography, along with the occasional need for magnetic resonance imaging or computed tomographic imaging as described in the next section.

Pulmonary arteriography works well if there is just the right amount of pulmonary venous obstruction. If this is too severe, and particularly if the duct is patent, it may be impossible to demonstrate the pulmonary veins because of loss of contrast medium into the systemic circulation. This happens despite the use of large doses of rapidly injected contrast medium and filming for 20 seconds or more. Furthermore, in the absence of pulmonary venous obstruction, pulmonary blood supply may be so high that serious dilution of contrast medium prevents optimal visualisation of the pulmonary veins. Mixed anomalous connection may be missed because of inadequate definition and simultaneous opacification of all the cardiac chambers. Selective left or right pulmonary arterial injection may improve recognition of the sites of drainage in mixed return. Pulmonary arterial wedge injection may be even better.

When opacified, the appearance of the vertical vein is characteristic (Fig. 24-23). So is the typical site of obstruction halfway along its course when it is present, representing the site where the vertical vein passes through the vise between the left pulmonary artery and left main bronchus. Anomalous connection to the portal vein is also characteristic. The pulmonary venous confluence, instead of being horizontal, tends to be vertical (Fig. 24-24). This gives the picture poetically termed the tree in winter.⁶⁰ When the anomalous connection is to the azygos or right superior caval vein, the course of the common pulmonary vein is frequently tortuous. Drainage to the coronary sinus is typified by the golf-ball appearance of the dilated coronary sinus in the frontal projection.⁶¹ Anomalous connection to the right atrium is much more difficult. The angiographic diagnosis depended on the recognition that right atrial opacification preceded that of the left atrium, but for none of the reasons listed above.⁶¹

Computed Tomographic Angiography and Magnetic Resonance Imaging

Technological advances in medical imaging have increased the utilisation of computed tomographic angiography and magnetic resonance imaging in the evaluation of patients

Figure 24-23 This selective injection, profiled in frontal projection, shows totally anomalous pulmonary venous connection to a left vertical vein.

Figure 24-24 This pulmonary arteriogram shows totally anomalous pulmonary venous connection to the portal vein. The position of the catheter in the left-sided inferior caval vein, and the heart lying to the right, together with the presence of totally anomalous pulmonary venous connection, strongly suggest right isomerism, which was indeed present in this patient.

with anomalous pulmonary venous connection.⁶² Given the inherent complexity involved in understanding the three-dimensional relationships in these patients, multi-planar imaging techniques such as magnetic resonance imaging and computed tomographic angiography allows one to understand the involved anatomy in more straightforward manner. Pulmonary venous connections with a particularly tortuous course, as is often seen with infracardiac connection or drainage via the azygous system, can be difficult to follow by echocardiography. These multi-planar modalities allow one to follow even the most tortuous vessels in a relatively simple fashion. As early as 1991, Masui and colleagues⁶³ found magnetic resonance imaging to be superior to both echocardiography and conventional angiography in patients with totally anomalous pulmonary venous connection. Since then, numerous other authors have endorsed its utility in these patients.^{64–68} Magnetic resonance imaging permits imaging in virtually any plane, allowing for accurate characterisation of the course and size of all pulmonary venous connections, along with other structural anomalies. Contrast-enhanced magnetic resonance angiography allows for three-dimensional reconstructions, which has been proven to be useful in these patients.^{69,70} In addition, magnetic resonance imaging allows for functional data including flow quantification and volumetric analysis. However, cardiac magnetic resonance imaging requires a combination of technical expertise and knowledge of cardiac anatomy that is not readily available in all centers, and time-consuming scanning protocols along with the need for transition to **equipment suitable** for use in magnetic resonance imaging limit the practicality of this imaging modality in the most critically ill infants.

High-resolution computed tomographic angiography using helical multi-detector scanners has proven to be a highly accurate alternative to conventional angiography in the diagnosis and characterisation of anomalous pulmonary venous connections.^{71–75} Newer scanners have cut the scanning time to a few seconds,⁷⁶ allowing most scans to be performed without sedation. Commercial software is readily available for three-dimensional reconstruction of these datasets, along with datasets from magnetic resonance angiography, permitting those with reasonable knowledge in congenital heart disease to manipulate the anatomy in such a way that is easily understandable.^{76,77} In contrast to magnetic resonance angiography, computed tomographic angiography allows for simultaneous three-dimensional reconstructions of additional thoracic structures, making it particularly useful in patients with the bronchopulmonary vise described above. In critically ill patients, computed tomographic angiography can be performed in an expeditious manner with minimal time away from the intensive care unit, without need to transition to specialised equipment. This can be useful for patients who are on extracorporeal membrane oxygenation.

Unlike what is seen with traditional angiography, magnetic resonance angiography and computed tomographic angiography will display contrast in multiple structures simultaneously. This is particularly useful when documenting mixed connections and in understanding spatial relationships in those with more complex anatomic arrangements (Figs. 24-25 and 24-26). Instead of using multiple injections and catheter courses to search for each pulmonary venous connection, all connections can

Figure 24-25 This computed tomographic angiogram reveals the complex pulmonary venous connections in a patient with mixed totally anomalous pulmonary venous connection. The right and left lower pulmonary veins (RLLPV and LLLPV) connect to a horizontal confluence, which leads into a vertical vein (VV). Pulmonary venous drainage from the left upper lung empties via multiple separate veins (arrows) as the vertical vein ascends. The vertical vein dives underneath the left azygos vein (star), resulting in stenosis before joining the rightward aspect of the left superior caval vein (LSCV). The right upper pulmonary vein (RUPV) connects with the leftward aspect of the right superior caval vein (RSCV). This image highlights the utility of CT angiography in evaluating complex pulmonary venous connections. I, inferior; L, left; R, right; S, superior.

Figure 24-26 In this patient with mixed totally anomalous pulmonary venous connection, the right pulmonary veins (RUPV and RLPV) and left lower pulmonary vein (LLPV) connect with the coronary sinus (CS). The left upper pulmonary vein (LUPV), however, connects with a vertical vein (VV) that drains into the left brachiocephalic vein (not imaged here). I, inferior; L, left; LA, left atrium; R, right; S, superior.

be located on one contrast injection. On the other hand, traditional angiography is likely superior in identifying pulmonary venous drainage from areas of the lung where there is little to no pulmonary blood flow, as these newer modalities have no acceptable substitute for a pulmonary artery wedge angiogram. When imaging patients with suspected supracardiac drainage, it may be useful to inject contrast from below the heart. Assuming the scan is performed with the first pass of contrast through the heart, as is standard procedure, any contrast in a venous structure above the heart can clearly be identified as pulmonary venous in origin (Fig. 24-27). This is particularly useful when trying to differentiate a left superior caval vein from a vertical vein. The converse can be applied to infracardiac connection.

Differential Diagnosis

Much of the basis of differential diagnosis has already been discussed and will not be repeated. As we shall see, pulmonary venous atresia also presents as totally anomalous connection with severe pulmonary venous obstruction. The two conditions, however, may be indistinguishable prior to surgery if no common pulmonary vein is seen by pre-operative imaging.

Unobstructed connection has to be distinguished from other conditions producing heart failure, mild cyanosis, and cardiomegaly with pulmonary plethora and right ventricular hypertrophy. The most important of these is complete transposition with large ventricular septal defect, in

Figure 24-27 This computed tomographic angiogram reveals all four pulmonary veins (RUPV, RLPV, LUPV, LLPV) connecting to a confluence (C), which leads to a vertical vein (VV) and then on to the left brachiocephalic vein (BCV) in a patient with supracardiac totally anomalous pulmonary venous connection. DAo, descending aorta; I, inferior; L, left; R, right; S, superior; SCV, superior caval vein.

which the second heart sound is commonly single. Atrio-ventricular septal defect with common atrium is easily distinguished by the typical electrocardiogram, showing a superior counter-clockwise frontal plane QRS loop. Totally anomalous connection to the left vertical vein has to be

distinguished from the laevoatrial cardinal vein found in association with mitral atresia and intact atrial septum. In both conditions, pulmonary venous blood flow is to a confluence via left vertical vein. In the case of the laevoatrial cardinal vein, the confluence is the left atrium, the pulmonary veins being normally connected.

Course and Prognosis

With medical treatment alone, three-quarters of all children with totally anomalous pulmonary venous connection uncomplicated by isomerism were dead or had undergone surgery by their first birthday.⁴¹ It is of interest that this poor survival occurred despite the fact that less than 10% had infradiaphragmatic anomalous connection. In one study, of 25 patients with pulmonary venous obstruction treated medically, only two survived their first year.⁵ In the postmortem study from central Bohemia, which relates to the time before advanced cardiac surgery, 95.8% of deaths occurred in the first year of life.⁷⁸ The only place for medical treatment, therefore, is in resuscitation of the critically ill neonate.

In the past, balloon atrial septostomy was shown to produce clinical improvement in the short term in some patients. It was impossible, however, to identify in advance those patients who would benefit from the procedure.^{79,80} At the time, septostomy was recommended as a procedure to buy time so as to permit the baby to undergo surgery at a size when the immediate surgical risk was lower. Recent improvements in surgical results, even at very young ages, militate strongly against this expectant policy. Furthermore, balloon atrial septostomy is technically more difficult than in complete transposition because two methods normally used to check that the catheter is in the left atrium do not apply. The left atrial saturation is not higher than the right, and pulmonary veins cannot be entered from the left atrium. Even using biplane screening, it can be difficult to distinguish a catheter positioned in the left atrium from one in a dilated coronary sinus. Sano and colleagues⁸¹ found that in no case did septostomy result in sufficient clinical improvement in critically ill patients to permit deferral of the operation. In patients with severely obstructed pulmonary venous return, stent placement in the area of obstruction can be considered as a temporising measure if surgery cannot be performed in a timely manner.^{82,83}

Management

Medical Treatment

In the current era, medical management consists solely of supportive measures in preparation for surgical management.

Surgery

With rare exception, neonatal repair is the standard of care. Totally anomalous pulmonary venous connection was the first condition in which the necessity of open heart repair in infancy was forced upon surgeons as a result of the appalling natural history, the lack of any adequate alternative by way of palliation and the potential for excellent long-term results if immediate survival could be achieved. The early results in infancy inevitably involved a high mortality.^{28,79,81,84,85} Operations at this time included those in which an anastomosis between the pulmonary venous

confluence and the left atrium was created but the interatrial communication was not closed; the common pulmonary vein, if obstructed, was not ligated.^{28,81,85} Though subsequent spontaneous closure of the interatrial communication was documented in some patients,⁸⁶ this staged approach is now rarely used. Surgical results have now greatly improved (Table 24-1). There used to be debate as to whether age or site of connection was the most important determinant of operative survival, but most recent studies have not shown either to be significant.⁸⁷⁻⁹⁴ Mortality in current era^{10,81,87-91,95,96} has been so low that analysis of risk factors has become challenging. Pre-operative pulmonary venous obstruction has been shown to be a risk factor in some series,^{87,88,90,91,96} but this effect may have been neutralised with improved perioperative care.^{87,91,92} Another study from Boston Children's found functionally univentricular physiology, as would be expected, to be a significant risk factor for hospital mortality.⁹⁰ In the series reported from the University of Alabama, the significant incremental risk factors for death were younger age, higher New York Heart Association class, higher pulmonary arterial systolic pressure, lower systolic pressure in the left ventricle, and previous balloon atrial septostomy.⁹⁷ Bando and colleagues⁸⁷ found emergency surgery, diffuse pulmonary vein stenosis, requirement of pre-operative inotropic agents, and post-operative pulmonary hypertensive events to be significant predictors of hospital mortality, while Bogers and colleagues⁸⁸ found that the use of circulatory arrest was a risk factor. In a study covering 50 years of surgical results in Toronto,⁹⁶ pulmonary venous obstruction, earlier year of repair, younger age at repair, and type of connection were all found to be significant predictors of death. Interestingly, and in contrast to other studies, the cardiac

form of connection was associated with an increased risk of surgical mortality. Failure to monitor pulmonary arterial pressure in the post-operative period was put forward as a risk factor for operative death in another series.⁹⁸

The inaccessibility of the pulmonary venous confluence behind the heart has meant that a bewildering variety of different surgical approaches have been employed for correction. Repair of anomalous connection to the coronary sinus involves either cutting back the mouth of the sinus into the left atrium and repairing the atrial septum in such a way as to leave the opening in the coronary sinus on its left side, or else using the technique promoted by Van Praagh and colleagues,¹² which involves removal of the muscular wall between the coronary sinus and left atrium and closing both the atrial septal defect and the mouth of the coronary sinus. Aeba and colleagues⁹⁹ described their experience over 30 years with repair of anomalous venous connection to the coronary sinus, finding favorable results with the use of autologous material rather than prosthetic material. Drainage to the right atrium or lower right superior caval vein can be repaired by shifting the atrial septum to its right side or by creating a prosthetic tunnel to lead pulmonary venous blood to the left atrium. The opening between the confluence and the right atrium may need to be enlarged. When connection is to other sites, the confluence must be reached by dislocating the cardiac apex forwards, by incising posterior pericardial attachments on the right so as to elevate the heart and caval veins and retract them to the left, by approaching through the transverse sinus or by cutting through the atrial septum and the posterior left atrial wall.¹⁰⁰ A confluence connected to a left vertical vein can also be approached from a left thoracotomy extended trans-sternally.¹⁰¹ A superior approach between the superior caval vein and ascending aorta, occasionally necessitating transaction of the aorta, can be useful for those with supracardiac or mixed drainage.¹⁰² Whatever the approach, the objective must be to create as wide an anastomosis as possible between the confluence and the left atrium. Given the small size of the left atrium that is commonly associated with this lesion, some surgeons chose to augment the atrium. However, this technique appears to be associated with late arrhythmias.⁹⁴

Because the left heart may have difficulty tolerating an acute increase in pulmonary venous return after surgery, resulting in low cardiac output, many surgeons leave the vertical vein intact after surgery.¹⁰³ After repair, flow through this high resistance pathway is thought to be negligible,^{100,104} although a follow-up study on these patients suggests that this vein often remains patent.¹⁰⁵ In 1994, a useful strategy was proposed by Stark.¹⁰⁶ The left atrial and systemic arterial pressures are measured after the patient is taken off bypass. The vertical vein is then snared. If occlusion of the vertical vein can be achieved without a rise in left atrial pressure and a fall in systemic pressure, then ligation of the vein is performed. Otherwise, the vein is left patent. Subsequent authors have validated the utility of this concept.^{107,108} To facilitate this strategy, percutaneously adjustable devices to ligate the vertical vein are under development, and have been found to be potentially useful.¹⁰⁹ The post-operative course is frequently marked by pulmonary hypertensive crises. Post-operative pulmonary hypertension in this population was traditionally managed with 100% oxygen and epoprostenol (prostacyclin),¹¹⁰ but nitric oxide has shown

promising results over the last 10 years.^{111–114} However, one should be cognisant of the rare possibility of paradoxical pulmonary hypertension with the use of nitric oxide in patients with poor left heart compliance.¹¹⁵

Results of Surgery

The late results of repair are, in general, excellent.^{116,117} The hazard function for death has become similar to that of the general population within about 24 months of operation.⁹⁷ Nonetheless, late pulmonary venous obstruction is not uncommon. This serious complication is poorly understood and occurs in patients with and without obstruction prior to surgery.⁹² It occurs in about 10% of all large surgical series and has remained stable over the last 30 years. Some authors have found it to be more common in patients with infracardiac or mixed drainage.^{55,93} Others have noted that it is more common in patients repaired at a younger age.¹¹⁷ The patient typically has undergone a reasonably smooth post-operative course and is discharged from hospital, only to be readmitted 4 to 6 weeks after operation with pulmonary oedema. It is more common in patients with a small pulmonary venous confluence and post-operative pulmonary hypertension.⁸⁷ In earlier studies, reoperation carried a high mortality and a strong chance of recurrence, whatever the nature of the obstruction. Few cases of survival beyond 1 year from the original operation were documented. In 1996, Lacour-Gayet and colleagues^{118,119} introduced a sutureless technique for reoperation using in situ pericardium with promising results. In this procedure, the pulmonary veins are incised from the ostia emptying into the left atrium out to the pericardial reflection, usually removing scarred tissue and left atrial wall. The presence of pericardial adhesions allows for the posterior pericardial cavity to be closed to the left atrium, occasionally reinforced by securing the resected free left dorsal atrial wall to the posterior pericardium with several sutures. A vascularised flap of pericardium can also be anastomosed to the right atrial wall used to create a pouch of in situ pericardium through which the right pulmonary veins can drain into the left atrium. Mid-term results from this technique have been encouraging.^{93,120–123}

Suggested pre-operative predisposing factors include hypoplasia of the pulmonary veins,^{16,47} the extension of muscle from intrapulmonary to extrapulmonary veins, thickening of the pulmonary venous wall and intimal proliferation.¹⁶ Most authors describe sclerosis or fibrosis as the substrate for progressive obstruction, though these statements are rarely supported by histology. Pre-operative pulmonary hypertension is present in most, but not all, of these patients.^{29,30}

A careful reading of the literature suggests that there are three groups of patients who have post-operative venous obstruction. In the first group, accounting for a minority of patients,^{84,100,124,125} post-operative pulmonary venous obstruction is clearly a consequence of a surgical error, such as construction of an insufficiently large anastomosis between the left atrium and the pulmonary venous confluence. Inadequate unroofing of the coronary sinus¹²⁶ is held by some to be preventable by using the approach suggested by Van Praagh and her colleagues.¹² In a second group, obstruction has been blamed, at least in part, on reaction of tissues either to the operation itself or to the prosthetic material employed.³⁰ In the third group, post-operative pulmonary venous obstruction is caused primarily by

unrelieved obstruction upstream to the post-operative pulmonary venous pathway. This usually occurs in drainage to the coronary sinus, the only variety in which the surgeon has not had to create an anastomosis between the heart and the pulmonary venous confluence.

The diagnosis is most simply made by colour flow mapping and Doppler interrogation. This will demonstrate a small anastomosis (Fig. 24-28) and/or a continuous, non-phasic relatively high-velocity Doppler flow signal and an enlarged right ventricle.⁵⁴ If none of these are present, venous obstruction is almost certainly absent. Cardiac catheterisation and angiography should be reserved for those patients for whom a site of obstruction cannot be identified, those whose clinical course and echocardiographic findings do not match, and those in whom placement of stents is intended. If catheter-based intervention is not planned, consideration should be given to magnetic resonance imaging or computed tomographic angiography as the imaging modality used to clarify questionable echocardiography findings. At catheterisation, injection of contrast medium is best made into the pulmonary veins or, failing that, into a wedged pulmonary arterial catheter.¹²⁷ Magnetic resonance imaging shows high-intensity signals in obstructed veins.¹²⁸ Both magnetic resonance angiography and computed tomographic angiography can delineate the precise anatomy of the stenosis (Fig. 24-29). The poor results of surgical relief of post-operative pulmonary venous obstruction have led to placement of stents across the stenoses either percutaneously or intraoperatively, but the results have either been disappointing, or else satisfactory over a very short term.^{93,129-133}

Incorporation of the pulmonary veins into the left atrium seems to have restored left atrial volume to normal in most of a small number of patients studied. Though the resting electrocardiogram is usually normal on 24-hour monitoring, supraventricular tachycardia, bradyarrhythmia and multi-form supraventricular and ventricular ectopic beats have been described.¹³⁴ Some groups have

Figure 24-28 In this zoomed up apical image, angled posteriorly, turbulent flow (star) can be seen at the surgical anastomosis between the confluence (C) and the left atrium (LA). Note that the Nyquist limit is 83 cm/sec. Pulmonary venous flow should not alias in this setting, unless there is obstruction. L, left; P, posterior.

Figure 24-29 In this patient with repaired totally pulmonary venous connection, computed tomographic angiography reveals the substrate for significant obstruction (arrow). The right lower pulmonary vein (RLPV) is stenotic at its junction with the left atrium (LA), and the left lower pulmonary vein (LLPV) appears to no longer be connected to the left atrium. The left pulmonary veins drain via a vertical vein (not imaged here), which was left patent at surgery. I, inferior; L, left; R, right; S, superior.

reported a high incidence of sinus node dysfunction, with three-tenths of subjects having chronotropic incompetence on exercise testing, but a very low incidence of significant arrhythmias.¹³⁵ Sudden late death 6 weeks post-operatively has been ascribed to documented sick sinus syndrome.¹³⁶ Another patient who required cardioversion post-operatively died suddenly at the age of 20.¹³⁷ These findings underscore the need for long-term follow-up for rhythm abnormalities. The chest radiograph returns to normal in 90% of patients, and 93% have a normal resting pulmonary arterial pressure. Pulmonary arterial pressure returns to normal even in patients with infradiaphragmatic connection.¹³⁸

A recent study by Kirshbom and colleagues¹³⁹ evaluated long-term results of patients with totally anomalous pulmonary venous connection repaired between 1983 and 2005. They reported an 84% 17-year survival rate, with most deaths occurring within a few months after surgery. Over 90% of their patients reported excellent or good overall health, and school performance was average or better in 69% of subjects. Pulmonary venous obstruction prior to repair and chromosomal or other non-cardiac abnormalities were found to be predictive of poor school performance and poor overall health. Another group reported 87% survival at 18 years, rising to 92% in those without additional cardiac or non-cardiac anomalies.⁹⁴ A group from western Canada further evaluated neurodevelopmental outcomes after neonatal repair and found that that mean developmental scores for psychomotor and mental functions were in the low range of normal, with socioeconomic factors predicting mental scores and higher post-operative lactate levels predicting lower psychomotor scores.¹⁴⁰ A report from patients repaired at the Children's

Hospital of Philadelphia between 1983 and 1996¹⁴¹ found that exercise performance was mildly impaired, but only 13% of patients had significant impairment of aerobic capacity below the 95% confidence limit for age. Almost half of the subjects were found to have deficits in one or more of the four domains of neurological outcomes assessed in the study.

ATRESIA OF THE COMMON PULMONARY VEIN

Anatomy

As we have discussed briefly in the previous sections, the essence of atresia of the common pulmonary vein is absence of functional connection between the pulmonary veins and the morphologically left atrium.²² The normally formed pulmonary veins converge immediately behind the left atrium to form a venous confluence that has either no outlet or a very limited outlet for pulmonary venous return. In these patients, atretic strands have been described connecting to the left atrium, right atrium, superior caval vein, along the oesophagus, and paratracheal venous plexuses^{1,22} (Fig. 24-30). The embryology has been discussed in the previous section.

Pathophysiology

There is no direct route for blood to enter either the left atrium or any systemic vein and yet patients have lived for up to a month with this condition.²² How oxygen reaches the systemic arteries is uncertain. One suggested route is

Figure 24-30 This specimen shows atresia of the common pulmonary vein between the pulmonary venous confluence and the left atrium, together with a tightly stenotic anomalous connection to the superior caval vein (SCV).

via bronchopulmonary venous anastomoses to the pleurohilar bronchial veins, which drain into the azygos, hemiazygos and brachiocephalic veins. Alternatively, blood could reflux from pulmonary capillaries into pulmonary arteries, and thence pass through bronchopulmonary arterial anastomoses and bronchial arteries into the systemic circuit.¹⁴²

The elevated pulmonary capillary pressure causes pulmonary oedema. Excess fluid may escape through dilated lymphaticocoronary sinuses, which have frequently been described in this condition.^{22,142-144} They also exist in obstructed totally anomalous pulmonary venous connection.¹⁶

Clinical Presentation and Investigation

The age at presentation, clinical findings, electrocardiogram and chest radiograph are as for totally anomalous connection with severe pulmonary venous obstruction. There may be a specific association between early spontaneous pneumothorax and atresia of the common pulmonary vein.¹⁴⁵ Echocardiographic findings have not always been diagnostic. A confluence with pulmonary veins connected to it, but with no flow in the veins, has been described in three patients. In two patients in the same series, colour flow mapping was said to show four veins draining to the left atrium.¹⁴⁶ Consequently, the diagnosis is difficult.

Imaging

Given the often small pulmonary venous confluence and severely obstructed flow through the pulmonary veins, this diagnosis can be very challenging to make using echocardiography.¹⁴⁷ The presence of exclusively right-to-left flow through the oval foramen and evidence of pulmonary hypertension, along with the inability to visualise a confluence, vertical vein, or pulmonary venous entry into the left atrium should suggest this diagnosis. Computed tomographic angiography can be attempted to define the anatomy. Considering the limited amount of flow into the pulmonary veins, the pulmonary veins may not be sufficiently opacified to clearly differentiate this entity from totally anomalous pulmonary venous drainage with severe obstruction. While cardiac catheterisation with pulmonary arterial wedge angiography may be necessary to fully define the anatomy, catheterisation is often poorly tolerated.¹⁴⁷ Characteristically, catheterisation reveals severe pulmonary hypertension with low arterial oxygen saturations in all vessels and cardiac chambers. Pulmonary angiography often fails to show any pulmonary veins at all, though the confluence can sometimes be recognised.^{142,143,146} As with computed tomographic angiography, it is very easy to confuse totally anomalous pulmonary venous connection with extreme pulmonary venous obstruction.

Management

There is no medical treatment. In the presence of a strongly supportive clinical situation, it may be necessary to pursue surgery despite the lack of a definitive anatomic diagnosis.¹⁴⁸ Surgical repair was often unsuccessful until the 1980s.^{143,149,150} More recently, a few centers have reported success using aggressive haemodynamic stabilisation techniques, often including extracorporeal membrane

oxygenation, and early surgical repair.^{146,148,151} Some of these patients were placed on extracorporeal membrane oxygenation for erroneously diagnosed pulmonary disease, but rapid improvement was achieved with clearing of the chest radiograph, leading to further investigation and then surgical repair.¹⁴⁶

UNILATERAL PULMONARY VENOUS ATRESIA

Unilateral pulmonary venous atresia is a very rare condition in which there is complete obliteration of luminal continuity between the pulmonary venous pathway of one lung and the left atrium. The majority of patients present within the first 3 years of life, displaying recurrent pulmonary infections, exercise intolerance, and/or haemoptysis. Less than 30 cases have been reported in the literature, with mortality approaching 40%.¹⁵² Diagnosis is best documented using pulmonary wedge angiography, although supporting information can be obtained using pulmonary perfusion studies. The affected lung often has poor ventilation and oxygenation, resulting in a large dead space, and the arterial supply is frequently hypoplastic. Over time, collateral blood supply to the affected lung develops, and flow in the ipsilateral pulmonary artery is reversed, resulting in a left-to-right shunt. Both reparative surgery and unilateral pneumonectomy have been successfully performed, although survival appears to be superior with pneumonectomy, particularly when diagnosed in older children and adults.^{152–155}

PARTIALLY ANOMALOUS PULMONARY VENOUS CONNECTION

Anatomy

The anomalous pulmonary venous connections are not always total. Partially anomalous connection exists where one or more of the pulmonary veins is connected to the morphologically left atrium, while the rest are connected to a systemic vein or the right atrium. The varieties of partial return are legion. It may be restricted to part of one lung (see Fig. 24-1). Alternatively, all of one lung may drain anomalously (see Fig. 24-2), or parts of both lungs may drain anomalously. All of one lung and part of the other may also be connected to anomalous systemic sites. The sites of anomalous connection can be to any of those discussed for totally anomalous connection. As with totally anomalous connection, depending on the extent of the malformation, all the anomalously connected veins may drain to the same site, or there may be mixed drainage. Obstructed drainage, however, has not to the best of our knowledge been described in the partial form, but it must be anticipated. By describing the amount of lung connected anomalously, the site and drainage and the presence of associated lesions, it is possible to describe clearly all the potentially bewildering complex variations.⁸

Some associations with partially anomalous pulmonary venous connection are so frequent as to warrant special consideration here, even though they are also considered in other chapters. The association between the sinus venosus interatrial communication and anomalous drainage of the right pulmonary veins is described in the next chapter. Indeed, in this setting it is the anomalous pulmonary

venous connection that produces the extracardiac conduit permitting interatrial shunting. We have discussed at length the necessary association of totally anomalous connection in the setting of isomeric right atrial appendages. The pulmonary veins frequently connect bilaterally when there are isomeric left atrial appendages, but in terms of the anatomic arrangement, this is not abnormal. It does, however, produce an obvious haemodynamic problem. This situation is described and discussed in detail in Chapter 22. The other association requiring special attention is the scimitar syndrome.^{156,157} In this lesion, the lower lobe of the right lung is hypoplastic, and is supplied with arterial blood from the descending aorta. Its pulmonary venous return is connected to the inferior caval vein. There are marked variations in the combination of abnormal connections, including sequestration of the abnormal lobe of the lung.¹⁵⁶

Morphogenesis

Presumably the canalising pulmonary vein in patients with partially anomalous connection will have made connection only with part of the intraparenchymal pulmonary venous plexus. Anastomoses between the unconnected pulmonary segments and the systemic venous plexuses persist and develop. There is no doubt that very bizarre patterns of drainage do occur that present a challenge to the embryologist, as discussed by Blake and colleagues.¹⁵⁸ This re-emphasises the inadvisability of basing descriptions of congenitally malformed hearts on embryological hypotheses.

Pathophysiology

Because pulmonary venous obstruction is rarely present with partially anomalous venous connections, the haemodynamic effects are almost always the result of an obligatory left-to-right shunt through the anomalously connected segments of lung. No right-to-left shunt occurs as a result of the anomalous connection. In older patients with pulmonary vascular obstructive disease, a right-to-left shunt can occur through an associated atrial septal defect.¹⁵⁹

When partially anomalous pulmonary venous connection occurs in association with an atrial septal defect, as it does more often than not,⁸ it is difficult to separate the haemodynamic effects of the two. Here, we will only consider the pathophysiology of cases with an intact atrial septum.

When only one pulmonary vein is connected anomalously, as in Figure 24-1, there may be no discernable consequences of the malformation. When there is complete anomalous connection of one lung, in contrast, be it right or left, the left-to-right shunt is usually greater than 50%. In other words, more blood flows through the anomalously connected lung than would be the case if it were normally connected.¹⁶⁰ The reason for this is almost certainly that pulmonary venous return is to the systemic side of the circulation, which has a lower mean pressure than the left atrium. When calculations of pulmonary vascular resistance are made, correcting for the proportion of blood flow that would normally go to the anomalously connected lobe or lobes, it appears that this resistance is the same in the normally and anomalously connected regions of lung.¹⁶¹ Therefore, it is not the vascular resistance that determines preferential flow to the anomalously connected lobe or lobes.

The left-to-right shunt at atrial level has the same consequences on the right heart and pulmonary circulation as does an atrial septal defect (see Chapter 25). Pulmonary hypertension is rare, except in some infants with scimitar syndrome who exhibit arterial, but not venous, muscularity in both lungs.¹⁶²

Presentation and Symptoms

Presentation is as for an atrial septal defect (see Chapter 25), except that some asymptomatic patients may present with an unexpected abnormality on chest radiograph (see below). Presentation with heart failure occurs rarely, as with interatrial defects at the oval fossa.¹⁶⁰ Patients with scimitar syndrome can present with recurrent pneumonia, wheezing, or haemoptysis.

The physical signs in patients with an associated atrial septal defect are as for the atrial septal defect. In those patients with an intact atrial septum, the signs are as for atrial septal defect with left-to-right shunt of comparable size, except that the second heart sound, though widely split, often varies normally with respiration.^{160,163} Sinus arrhythmia is common. This is presumably because changes in intrathoracic pressure affect the atria to different degrees, as in normal individuals. This contrasts with what happens in the presence of a large atrial septal defect. Therefore, if a patient has the pulmonary ejection systolic murmur of an atrial septal defect and yet has physiological splitting of the second heart sound, the diagnosis is highly likely to be partially anomalous connection with intact atrial septum.

Investigations

Chest Radiography

The general appearances of the heart and pulmonary vessels will be exactly as for an atrial septal defect with a comparable left-to-right shunt. But the anomalous pulmonary vein may also be evident. A snowman appearance would suggest return to the left vertical vein; in older patients with return to the inferior caval vein, the anomalous pulmonary vein is always visible.^{159,160} We have already highlighted the importance of this appearance as seen in the scimitar syndrome.¹⁵⁷ The hypoplasia of the right lung, pulmonary sequestration, and secondary right-sided location of the heart usually accentuate the scimitar sign as seen in the frontal projection of the right lung. It is formed by the anomalous right pulmonary vein (Fig. 24-31), though rotation of the heart to the right may completely obscure the scimitar in infants.¹⁶² Exceptionally, such a scimitar may be formed by a common right pulmonary vein that descends towards the diaphragm but ascends to connect normally to the left atrium^{164–166} or to the left atrium and the inferior caval vein.¹⁶⁶

Electrocardiography

When the partially anomalous connection is associated with an atrial septal defect in the oval fossa, or the atrial septum is intact and the anomalous connection is supracardiac or to the right atrium, the electrocardiogram is identical to that of an atrial septal defect. Specifically, V_1 shows an rsr' or rsR' , or rarely a QR, or pattern in V_1 . Partial, return to the inferior caval vein with intact atrial septum is characterised by a terminal s or S wave in V_1 .¹⁶⁰

Figure 24-31 Plain chest radiograph showing the scimitar syndrome. There is only mild hypoplasia of the right lung; consequently, the bulk of the heart is still in the left chest. (Original photograph kindly supplied by the late Dr Simon Rees, National Heart Hospital, London, United Kingdom.)

Echocardiography

As with totally anomalous pulmonary venous connection, echocardiography is primary means of defining pulmonary venous anatomy in these patients. As when dealing with all patients, echocardiographers should persistently attempt to identify pulmonary venous connections from all portions of the lung into the heart. Increased or atypical flow in the superior or inferior caval veins should alert one to the possibility of partially anomalous pulmonary venous connection (Fig. 24-32). Nevertheless, partially anomalous venous connection is the Achilles heel of the echocardiographer, particularly when associated abnormalities mask

Figure 24-32 In this high right parasternal view, the right upper pulmonary vein (RUPV) can be seen entering the superior caval vein (SCV). P, posterior; S, superior.

its clinical effects. There are three problems. First, even when all four pulmonary veins are normally connected, they may not be imaged. In particular, fusion of two pulmonary veins on one side into a common pulmonary vein may not be recognised, though it is a common normal variant. Second, some patients have more than four pulmonary veins. For example, if a patient has a right middle

lobe draining normally to the left atrium, but a right upper lobe draining to the superior caval vein, the echocardiographer may visualise four pulmonary veins entering the left atrium and erroneously assume completely normal pulmonary venous connections are present (Fig. 24-33). Third, the great clue to the diagnosis of totally anomalous pulmonary venous connection, namely a collecting pulmonary venous channel, or confluence, is almost invariably missing in partially anomalous connection. In short, partially anomalous venous connection can be positively and reliably diagnosed, particularly if it is via a left vertical vein, but it can rarely, if ever, be ruled out, even using colour flow mapping and transoesophageal echocardiography.^{64,167} Surgeons should be aware of this caveat in diagnosis. Partially anomalous pulmonary venous connection is occasionally identified by fetal echocardiography.⁵⁶

Computed Tomographic Angiography and Magnetic Resonance Imaging

As with totally anomalous pulmonary venous connection, computed tomographic angiography^{62,73,74,168,169} and magnetic resonance imaging^{64,67-69} are very accurate noninvasive methods to evaluate anatomy in patients with partially anomalous pulmonary venous connection (see Fig. 24-33). Computed tomographic angiography is particularly useful for patients with scimitar syndrome, given that this modality allows for simultaneous evaluation of lung parenchyma and pulmonary venous anatomy (Fig. 24-34). Both methods are also valuable in screening for pulmonary venous anomalies in patients being assessed for Fontan-like operations.¹⁷⁰ Such screening is necessary because failure to recognise the presence of an anomalous vein will result in an important left-to-right shunt and elevation of systemic venous pressure.

It is important to distinguish between partially anomalous connection to a left vertical vein and persistence of the left superior caval vein.¹⁷¹ Traditionally, the characteristic finding by magnetic resonance imaging was a lateral break

Figure 24-33 This computed tomographic angiogram shows the anomalous connection of the right upper pulmonary vein (RUPV) to the superior caval vein (SCV). Note that there are four pulmonary veins (LUPV, LLPV, RMPV, RLPV) entering the left atrium (LA). This highlights the challenge in detecting this anomaly by echocardiography. I, inferior; L, left; R, right; RPA, right pulmonary artery; S, superior.

Figure 24-34 A, This computed tomographic angiogram on a patient with scimitar syndrome shows the right pulmonary venous confluence (star) draining into the junction between the right atrium (RA) and inferior caval vein (ICV). B, In this same study, reconstructed with settings appropriate for evaluation of the lung fields, one can see the relative hypoplasia of the right lung. A, anterior; I, inferior; L, left; P, posterior; R, right; S, superior.

in the complete ring created by fat surrounding the superior caval vein in the transverse plane.¹⁷² Newer protocols for imaging, incorporating three-dimensional reconstructions, make this distinction much more straightforward.

Cardiac Catheterisation and Angiocardiology

Cardiac catheterisation is rarely indicated for these patients. A combination of non-invasive imaging techniques will document the pathophysiology already described. In diagnosing partially anomalous pulmonary venous connection, a step-up in oxygen saturation in the superior caval vein, the brachiocephalic vein, or the inferior caval vein is suggestive of anomalous pulmonary veins draining into the respective site.¹⁷³ Entry to the anomalous veins may be achieved as for totally anomalous connection. In patients with scimitar syndrome and a hypoplastic right lung, measurement of oxygen saturations in the anomalous right pulmonary veins could be helpful when deciding whether to pursue surgery, as repair is unlikely to be advantageous in patients with pulmonary venous desaturation.

To demonstrate drainage outside the heart, pulmonary arteriography and selective pulmonary venous angiograms may be performed as for totally anomalous connection (Fig. 24-35). It should be noted that pulmonary angiography alone may not be sufficient to fully document anomalous pulmonary venous drainage, particularly anomalous drainage from the right lower lobe.¹⁷³ In the case of the scimitar syndrome, selective injection of the systemic arterial supply to the lungs is also essential (Fig. 24-35B). Along these lines, if there is dual arterial supply (both systemic and pulmonary) to any portion of the lung, embolisation of the aorto-pulmonary collateral in the catheterisation laboratory should be considered.

Differential Diagnosis

The main differential diagnosis is an atrial septal defect in the oval fossa, which has been discussed at length already. In most cases, particularly when associated with atrial septal defect, it is not critical that the anomalous connection be diagnosed pre-operatively, since surgery can usually be adjusted accordingly. Therefore, invasive investigation of a typical atrial septal defect is not justified simply to rule out partially anomalous pulmonary venous connection. The only possible exception is connection of both left pulmonary veins to a vertical vein. This then involves a rather

more complex operation than simple closure of an atrial septal defect or diversion of other forms of partially anomalous connection.

Anomalous connection of a solitary pulmonary vein may give no more than an unimpressive systolic murmur and can, therefore, be confused with a normal heart. Even if this error is made, the patient will not suffer, since the haemodynamic consequences are trivial and there is no risk of bacterial endocarditis.

Course and Prognosis

The course and prognosis for partially anomalous pulmonary venous connection are probably similar to those of an isolated atrial septal defect with a comparable left-to-right shunt. Pulmonary vascular obstructive disease is rare but undoubtedly occurs.^{174,175} Prognosis for patients with scimitar syndrome is worse than other types of partially anomalous pulmonary venous drainage, particular among those who develop symptoms within the first year of life.¹⁷⁶

In the particular case of anomalous connection of all the veins from one lung, there is a risk that death may result if the respiratory function of the normally connected lung is compromised. In that case, fully saturated pulmonary venous blood will only be recirculated to the lung, and relatively desaturated blood will be sent to the body.¹⁷⁷

Management

Medical Treatment

Medical management is as for any atrial septal defect and is rarely necessary.

Surgery

As the repair for partially anomalous pulmonary venous connection associated with a sinus venosus defect is described in Chapter 25, the following discussion covers only those patients in which the atrial septum is intact or with only a patent oval foramen. Surgical repair is recommended if the ratio of pulmonary-to-systemic flow is greater than 2 to 1.^{160,173,175,178} The techniques are broadly similar to those already described for totally anomalous connection. In the case of supracardiac or intracardiac drainage, unilateral anomalous connection of all pulmonary veins will not be associated with a collecting channel behind the left atrium. This complicates repair. When the right veins

Figure 24-35 Selective angiography in the scimitar syndrome displayed in the frontal projection. A, The pulmonary arteriogram, filmed in its late stages, demonstrates that the pulmonary veins return by two routes to the heart: one a tortuous vein to the right atrium, and one a descending pulmonary vein to the inferior caval vein. B, A selective injection into a branch of the descending aorta demonstrates the anomalous systemic arterial supply.

are connected to the superior or inferior caval veins, or to a hepatic vein, it is usually possible to create a baffle within the caval vein and right atrium so as to direct blood to the left atrium.¹⁷⁹ Interposition grafts made of polytetrafluoroethylene have been used, in place of a baffle, to direct blood to the left atrium.¹⁸⁰ Direct anastomosis of the right pulmonary vein to the left atrium has also been achieved.^{160,181} This approach can be performed off bypass through a right thoracotomy, and avoids the possibility of stenosis developing at the margins of the baffle.¹⁸² Some patients with scimitar syndrome benefit from a concomitant resection of the pulmonary sequestration, if present.

The usual method of repair of unilateral connection of all the veins from the left lung to a left vertical vein is to connect the common left pulmonary vein to the amputated stump of the left atrial appendage.¹⁸³ More or less the same technique was used in one series, being accomplished without early or late death, even though the repairs were performed without cardiopulmonary bypass.¹⁸⁴ On the grounds that this kind of anastomosis, like all venous anastomoses, is liable to late stenosis, some¹⁸⁵ have advocated dividing the vertical vein and incising it longitudinally to form a cobra-head, which was then anastomosed to the left atrium between the left atrial appendage and the entrance of the right pulmonary vein. The circumference of this oblique anastomosis is clearly much larger than the circumference of the vein. Repair of partially anomalous pulmonary venous return should be carried out electively before a child goes to school. The mortality is less than 1%. The long-term results of venous anastomosis should be followed with care, but there is limited literature available documenting these results.

ANOMALOUS PULMONARY-TO-SYSTEMIC COLLATERAL VEINS AND THE LAEVOATRIAL CARDINAL VEIN

Anomalous pulmonary-to-systemic collateral veins, along with the so-called laevoatrial cardinal vein (see Fig. 24-3), are frequently found in association with more serious causes of obstruction of pulmonary venous return, such as an intact atrial septum with left atrioventricular valvar atresia, aortic stenosis or aortic atresia, and divided left atrium. They act as safety valves, enabling pulmonary venous return to escape to the systemic circulation, and producing the arrangement of anomalous pulmonary venous drainage with anatomically normal pulmonary venous connections.²¹ In these circumstances, the clinical presentation will be generally dominated by the lesion causing the pulmonary venous obstruction. If the laevoatrial cardinal vein is of insufficient caliber to provide unobstructed passage of pulmonary venous blood to the systemic circulation, the patient may present with profound cyanosis. Along those lines, Vance¹⁸⁶ reported placement of a stent in the laevoatrial cardinal vein as a bridge to surgery in a patient with severe pulmonary venous obstruction due to an intact atrial septum in the setting of mitral atresia.

The presence of the anomalous collateral channels, or the laevoatrial cardinal vein, will emerge as a chance finding on traditional angiography,¹⁸⁷ cross sectional echocardiography,⁴⁹ or computed tomographic angiography.^{188,189} At first glance, either lesion may be mistaken for totally anomalous connection to the left vertical vein, or the right superior caval vein (Fig. 24-36). In both instances, pulmonary venous

Figure 24-36 The picture shows a so-called laevoatrial cardinal vein, which originates from the roof of the left atrium and, as shown by the arrows, passes behind the superior caval vein (SCV) before terminating in the systemic venous channel. It is easy to mistake this for an anomalous pulmonary venous connection, but as can be seen, the pulmonary veins join in normal fashion to the left atrium.

blood returns to a confluence, which then drains via a vertical vein. In anomalous connection to the left vertical vein or right superior caval vein, the confluence is distinct from the left atrium and its appendage. In these other conditions, the effective confluence is the left atrium (see Fig. 24-3). Confusion of these two entities can be disastrous. Distinction is more difficult in that hypoplasia of the left heart can be associated not only with normally connected but abnormally draining pulmonary veins, but also with totally anomalous pulmonary venous connection. Nowadays, distinction is usually possible using cross sectional echocardiography with colour flow mapping. Another lesion to be distinguished from anomalous venous connection is the fistulous channel connecting the left upper pulmonary vein to the brachiocephalic vein, or similar connections. This can occur as an isolated abnormality, giving rise to a characteristic, if exceptionally rare, clinical picture.^{188,190,191} Patients present without symptoms but with a venous hum under the left clavicle. Unlike the benign systemic venous hum at the same site, no amount of movement of the head or compression of jugular veins will abolish it.

STENOSIS OR ATRESIA OF INDIVIDUAL PULMONARY VEINS

Anatomy

Individual pulmonary veins can be stenosed at their junction with the atrium (Fig. 24-37), or exhibit tubular hypoplasia over a significant intra- and extrapulmonary distance (Fig. 24-38).^{1,192} It is only when several veins are involved that the condition becomes clinically manifest. Pulmonary venous stenosis can also result from acquired causes, such as constrictive pericarditis, mediastinitis, pulmonary tuberculosis or invasion by tumour.

Figure 24-37 The heart from this patient, who died due to pulmonary venous stenosis, has been dissected to show the tubular hypoplasia of each of the four individual pulmonary veins (arrows).

Pathophysiology

Stenosis or atresia of a solitary pulmonary vein unassociated with other severe cardiac anomalies has not, to our knowledge, been described. Most commonly, both pulmonary veins from one lung are affected. Just under half the patients described have had other congenital heart defects, varying from the simple to the complex.¹⁹³ Pulmonary venous pressure becomes elevated on the afflicted side as a result. Pulmonary arterial hypertension usually ensues, though patients have been described with a normal pulmonary pressure.¹⁹⁴ In the case of unilateral pulmonary venous atresia, or severe stenosis, pulmonary blood flow will be largely or completely diverted to the contralateral lung. The result is that the pulmonary artery on the obstructed side may be unusually small, and there will be none of the usual signs of pulmonary venous hypertension.^{195,196} The greater the number of pulmonary veins obstructed, and the more severe the obstruction, the more severe will be the pulmonary hypertension. Elevation of right ventricular end-diastolic pressure may result in a right-to-left shunt through the oval foramen.¹⁹⁷

Presentation and Symptoms

Lesions of a single pulmonary vein might well be asymptomatic and not produce problems. When sufficient veins are affected, patients usually present in early infancy, though sometimes presentation is delayed until early childhood. Dyspnea and repeated pulmonary infections with failure to thrive are the rule.¹⁹⁸ Many patients have haemoptysis and, occasionally, cyanosis.^{154,155}

Patients generally look unwell, with tachypnea, retractions, and occasional cyanosis. There are frequently rales in

Figure 24-38 In this patient, who also suffered severe pulmonary stenosis in life, the stenotic sites are at the junctions of the individual pulmonary veins with the body of the left atrium. Note the dilated pulmonary veins, and the hypertrophied walls of the left atrium.

the chest, and sometimes evidence of right heart failure.¹⁹⁹ One patient had signs of right pleural effusion.¹⁹⁶ Murmurs are usually unimpressive, and the heart sounds unremarkable apart from accentuation of pulmonary closure. Occasionally, there is a pulmonary ejection click.

Investigations

Chest Radiography

A chest radiograph is the most likely examination to suggest the diagnosis. Although the chest radiograph may be normal in the early stages,¹⁹⁵ marked abnormality is the rule. The heart is usually normal in size or slightly enlarged, with prominence of the pulmonary trunk. The lungs show a reticular appearance or ground-glass opacification, with or without Kerley B lines in the region of the obstructed vein or veins. There may be hypoplasia of the lung on the affected side. Therefore, the regional nature of the abnormality is the key to the diagnosis except when all the pulmonary veins are affected.²⁰⁰ It is important to realise that preferential flow occurs to the contralateral lung when unilateral pulmonary venous stenosis or atresia is associated with a left-to-right shunt. If there are no specific indicants of pulmonary venous hypertension on the same side, the appearance may be misinterpreted as being caused by pulmonary arterial stenosis.

Electrocardiography

Right atrial and right ventricular hypertrophy without left-sided changes are almost invariably found by electrocardiography.¹⁹⁸

Echocardiography

It is imperative that all four pulmonary veins be visualised by echocardiography in order to screen for this diagnosis. When pulmonary venous stenosis is suspected, colour and spectral Doppler of each pulmonary vein will document

Figure 24-39 In this zoomed apical four-chamber view, shown with and without colour Doppler, an area of turbulence (arrow) can be seen as the left lower pulmonary vein (LLPV) enters the left atrium (LA). L, left; S, superior.

the presence or absence of stenosis.^{201–203} In some patients, transoesophageal echocardiography will be required. Turbulence or a focal increase in flow velocity with a continuous, non-phasic flow pattern distally in a pulmonary vein suggests stenosis (Fig. 24-39).

Radionuclide Angiography

Nuclear perfusion lung scans, following injection of labeled technetium, show reduced or absent perfusion in the region of lung drained by the vein or veins that are obstructed.¹⁵⁴ In two patients, ventilation on the affected side was said to be reduced.^{155,196}

Cardiac Catheterisation

Cardiac catheterisation documents the pathophysiology described. Provided that the pulmonary vein is not atretic, it is helpful to record withdrawal traces from pulmonary veins to left atrium, though care should be employed in interpreting the findings. In neonates particularly, pressure gradients may be found in normal pulmonary veins because the veins are not much larger than the catheter. If the left atrium cannot be entered, or the pulmonary veins are atretic, pulmonary capillary wedge pressures should be recorded in upper and lower regions of both lungs, preferably simultaneously with a left-ventricular end-diastolic or left atrial pressure.²⁰⁴ It should be remembered that a normal wedge pressure does not necessarily exclude pulmonary venous stenosis.²⁰⁵ This is because, when a catheter is wedged in a pulmonary arteriole, the capillary, venule, and vein beyond the catheter act as an extension of it; the catheter, may, therefore, reflect left atrial pressure rather than pulmonary venous pressure proximal to the stenosis.

Traditional Angiography

Pulmonary angiography will show slow clearance of contrast medium from one lung in the case of unilateral pulmonary venous stenosis. If this is sufficiently severe, or the pulmonary veins are atretic, the contrast medium may well run to-and-fro into the pulmonary artery on that side without ever opacifying the pulmonary veins.^{195,196} Pulmonary arteriography is often disappointing in demonstrating the precise anatomy of pulmonary venous stenosis. Pulmonary arterial wedge angiography may well do better (Fig. 24-40).¹²⁷ Selective pulmonary venous injection, if possible, is ideal (Fig. 24-41).¹⁹³

Computed Tomographic and Magnetic Resonance Angiography

Provided that there is more than trivial flow through the pulmonary veins, both computed tomographic and magnetic resonance angiography should be able to show the precise anatomy of the stenosis well (Fig. 24-42).

Figure 24-40 In this patient, pulmonary arterial wedge injection clearly demonstrates the right lower pulmonary vein but reveals a severe stenosis as it enters the left atrium. (Original photograph courtesy of the late Dr Robert Freedom, Hospital for Sick Children, Toronto, Ontario, Canada.)

Figure 24-41 In this patient, left pulmonary venous stenosis is demonstrated by selective injection in the pulmonary vein. (Original photograph courtesy of the late Dr Robert Freedom, Hospital for Sick Children, Toronto, Ontario, Canada.)

Differential Diagnosis

Stenosis or Atresia of One or Two Pulmonary Veins

Stenosis or atresia of one or two pulmonary veins must be distinguished from pulmonary infection, which is far more common. Lack of fever, elevation of sedimentation rate, leucocytosis, and response to antibiotic should lead to the suspicion of pulmonary venous stenosis.

Stenosis or Atresia of Most or All Pulmonary Veins

Stenosis or atresia of most or all pulmonary veins must be distinguished from other causes of generalised pulmonary venous hypertension. The absence of severe cardiomegaly distinguishes pulmonary venous obstruction from left ventricular disease and mitral regurgitation. Mitral stenosis and supralvalvar mitral ring almost always exhibit diastolic murmurs and are easily recognisable on echocardiography, as is divided left atrium. Totally anomalous pulmonary venous connection and atresia of the common pulmonary vein only present a problem in cyanotic patients, and

Figure 24-42 This computed tomographic angiogram shows stenosis (arrow) of the left upper pulmonary vein (LUPV) as it enters the left atrium (LA) in a patient after radio-frequency ablation for atrial fibrillation. A, anterior; L, left; P, posterior; R, right.

echocardiographic demonstration of a pulmonary venous confluence will rule out stenosis or atresia of individual pulmonary veins.

The most likely disease to cause confusion is pulmonary veno-occlusive disease. Here, however, the pulmonary capillary wedge pressure is usually normal, and no obstruction can be demonstrated in the pulmonary veins either by measurements of pressure or angiography. Pulmonary veno-occlusive disease is very rare in young infants.

Course and Prognosis

Without surgical treatment, most patients will die before reaching adulthood, and frequently much sooner.^{154,193} An analysis using the Pediatric Cardiac Care Consortium database²⁰⁶ identified 31 patients, from a total group of 98,126 patients, who had primary pulmonary venous stenosis. Of these, three-fifths either died or underwent lung transplantation. Four-fifths of those with a mean pulmonary arterial pressure higher than 33 mm Hg experienced death or lung transplantation.

Management

Medical Treatment

Standard anti-failure treatment will relieve the immediate problem, but is unlikely to be effective for long.

Surgery

Localised atresia or stenosis has been successfully treated by patch grafting,^{195,202,204} side-to-end anastomosis of the vein to the left atrium,¹⁵⁴ excision of an obstructing membrane at the junction of the pulmonary vein with the left atrium,²⁰⁷ or by the so-called sutureless technique described above for treatment of post-operative stenosis after repair of anomalous pulmonary venous connection.^{121,123} Of

these, the sutureless technique is currently the most promising. Not only was this technique found to have improved freedom from reoperation and death compared to traditional surgical techniques, but despite the absence of retrocardiac adhesions, operative mortality was not increased compared with that of the patients who had a sutureless repair as a reoperation.

While catheter-based interventions using stents, and cutting balloons, have been successful in adults with pulmonary venous stenosis occurring after catheter ablation for atrial fibrillation,^{208–210} the long-term results for other causes of pulmonary venous stenosis have been disappointing.^{131,132,193,206,211–213}

The only effective treatment for long-segment atresia or severe pulmonary venous hypoplasia is pneumonectomy, when the disease is unilateral and the objective is to cure massive haemoptysis.^{196,200}

PULMONARY VARIX

Pulmonary varix is a rare anomaly, presenting as a mass in the lung on routine chest radiograph, usually between the fourth and sixth decades. It has been found in patients as young as 7 years. It is usually observed in the right upper pulmonary lobe. The differential diagnosis includes all other space-occupying lesions, but can be established by pulmonary angiography, magnetic resonance angiography, computed tomographic angiography,^{214,215} or if it is related to the heart, by transoesophageal echocardiography.²¹⁶ This lesion is considered benign, and treatment is generally reserved for those who experience complications such as haemoptysis or cerebral embolic events, or for those in whom growth of the defect results in compression of surrounding structures.²¹⁷ Death caused by rupture has been reported.^{218–220}

Interatrial Communications

ROBERT F. ENGLISH, ROBERT H. ANDERSON, and JOSÉ A. ETTEGUI

Holes between the atrial chambers are important congenital cardiac anomalies, both because they are relatively common, and because they are more nearly completely correctable than most other cardiac malformations, the more so in the new era of catheter intervention. It may be difficult, nonetheless, to diagnose the presence of such holes, and often there is no suspicion of organic cardiac disease during infancy and early childhood. Moreover, the anatomical arrangement, on occasion, is more complex than mere deficiency of the floor of the oval fossa. It is these anatomical features that underscore our specific description of holes between the atrial chambers, rather than the more usual reference to atrial septal defects. We will emphasise the subtle differences between true atrial septal defects and interatrial communications in our initial section devoted to morphology. It is the lack of early symptoms, nonetheless, coupled with the added subtlety of the physical findings, which delay the diagnosis, sometimes until well into adult life, or even until middle or old age. In contrast, if the left-to-right shunt is large, clinical diagnosis can still be made on the basis of a meticulous cardiac physical examination. The chest radiograph and electrocardiogram usually support such diagnosis, but echocardiography and Doppler studies are diagnostic in virtually all cases. Therapeutic intervention during childhood, after documentation of an important shunt at atrial level, should now result in a normal life expectancy, free of cardiac morbidity, and with the increasing use of devices inserted on catheters, without the need for thoracotomy.

INCIDENCE

Reports of incidence of holes between the atrial chambers have varied between the lesions accounting for one-twentieth to one-tenth of all congenital cardiac anomalies.¹⁻³ To a large extent, these discrepancies may depend on the definition of holes between the atria. In the autopsy room, it may be difficult to distinguish those patients with deficiencies of the floor of the oval fossa from probe patency, in which the flap of the foramen had been competent during life, with the atrial communication being only potential. Probe patency is remarkably frequent, being discovered in up to one-third of all the hearts, irrespective of age.^{4,5} With the finding that probe patency may underscore some cases of migraine,⁶ diagnosis of this normal finding has achieved increased significance. Irrespective of the incidence of probe patency, the variable prevalence of defects noted in the different clinical series is related to the ages of the patients within the series. Thus, a series of infants and young children will have a relatively low prevalence of a clinically apparent interatrial communication as the primary defect, while a series of adults with congenital cardiac disease will have a high

prevalence. This is due both to the attrition of patients with other severe and life-threatening defects, and to the frequent delay in diagnosis of an atrial defect until young adulthood. The prevalence also depends upon whether clinically unimportant interatrial communications accompanying more serious defects are included in the series. Prevalence of clinically significant defects, therefore, can perhaps best be judged by the relative frequency of the necessity for surgical closure. When preparing this chapter for the second edition of this book, we noted that, over a period of 25 years, more than 6000 infants and children under the age of 19 years had undergone surgery for treatment of congenital cardiac malformations at the Children's Hospital of Pittsburgh. Of these children, an interatrial communication was the sole, or most important, anomaly in one-tenth of the series. Surgical closure of a hole between the atria had been undertaken in a further one-sixth, in conjunction with repair of other anomalies. The excellent records kept of autopsies performed at Children's Hospital in Pittsburgh also permit similar observations concerning recognition at postmortem examination. So, during that 25-year period, just over 1000 infants and children with congenital cardiac malformations had come to autopsy. Of these, none had died because of a hole between the atria, but an interatrial communication had been observed as an incidental finding in one-sixth. The oval foramen was found to be probe patent in nearly two-fifths of the specimens. Holes between the atria are said to be more common in females, with one report suggesting a ratio of this finding in two females to every male.⁷ Others,⁸ in contrast, found a slight predominance of males. The defects may be found in higher prevalence in populations residing at higher altitudes.⁹

AETIOLOGY

There are no known intra-uterine events which predispose to deficient atrial septation, and most cases occur sporadically, with no family history of congenital cardiac disease. There is a significant familial incidence when the atrial septal defect is associated with certain skeletal abnormalities of the forearm and hand, the so-called Holt-Oram syndrome.¹⁰ This has now been shown to be due to mutations of the *Tbx5* gene, a member of the *Brachyury* family of genes.¹¹ When observed in families, atrial septal defects are also associated with prolongation of the PR interval.¹² There is also, occasionally, a familial incidence without these associated abnormalities of the skeleton or atrioventricular conduction. In the patients undergoing surgical closure in Pittsburgh over the period of 25 years discussed above, from one to five close relatives were recognised in nine families, giving a total of 18 familial cases.

MORPHOLOGY AND CLASSIFICATION

The accurate classification of interatrial communications is important, not because the location of the defect alters haemodynamics, but rather because of differences in the incidence of associated anomalies, differences in techniques of surgical repair, and implications for the option of interventional closure. For the surgeon, when planning repair, it is important to be aware of the anomalously connecting pulmonary veins which are the essence of the sinus venosus defect, or of the atrioventricular valvar abnormalities which are part and parcel of the ostium primums defect. This latter lesion, of course, is an atrioventricular septal defect with common atrioventricular junction, but with shunting between the chambers confined at atrial level. It will be described in a chapter to follow. As an extreme example of anatomical difficulties, nonetheless, it may be difficult to recognise a hole at the mouth of the coronary sinus as an interatrial communication, and not simply enlargement of the coronary sinus, if the diagnosis has not been established prior to attempted closure, either by surgery or interventional catheterisation.

The Normal Atrial Septum

Understanding the morphology, and classification, of interatrial communications is itself dependent on a thorough knowledge of the anatomy and extent of the atrial septum. This is because, as we will emphasise, some of the defects which permit shunting of blood at atrial level are outside the confines of the atrial septum. The septum has markedly different characteristics on its morphologically right and left sides. When the right atrium is opened through a wide incision, it seems at first sight that a large expanse of the atrial walls between the orifices of the superior and inferior caval veins and the attachment of the septal leaflet of the tricuspid valve are interposed between the right and left atriums (Fig. 25-1). Sectioning the heart shows that only a small part of this area interposes as a common wall between the atrial cavities, specifically the floor of the oval fossa and its antero-inferior muscular margins (Fig. 25-2). The superior part of the rim, often called the septum secundum, is produced because of infolding of the atrial walls between the mouth of the superior caval vein and the insertion of the right pulmonary veins to the left atrium. This is the area known to surgeons as Waterston's, or Sondergaard's, groove. A substantial cleavage plane, filled by extracardiac fat in the adult heart (Fig. 25-3), extends down to the margin of the fossa.

The internal aspect of this groove represents the prominent muscle bundle which separates the fossa from the orifice of the superior caval vein. It is described appropriately as the superior rim of the fossa, or the superior interatrial fold. More anteriorly, the rim continues as the antero-superior atrial wall overlying the aortic root. This part is well described as the aortic rim of the fossa (see Fig. 25-2). When traced rightwards as viewed in attitudinally appropriate orientation, the rim of the fossa becomes directly continuous with the wall of the inferior caval vein. It is along the antero-inferior margin of the fossa that the morphology is most complicated. This part of the rim separates the fossa from the orifice of the coronary sinus, the mouth of the coronary sinus itself being separated from

Figure 25-1 Opening the right atrium gives the impression, at first sight, that an extensive area of wall interposes between its cavity and that of the left atrium, as shown by the dotted circle. Sectioning along the line shows the true arrangement, as seen in Figure 25-2.

Figure 25-2 The heart shown in Figure 25-1 has been sectioned along the yellow line shown in that figure. As can be seen, the rims adjacent to the rightward margins of the openings into the systemic venous sinus of the superior (SCV) and inferior (ICV) caval veins and the aorta are infoldings of the walls, as is the superior rim. It is only the floor of the oval fossa (star), and the antero-inferior margin, that represent true septal structures (see Fig. 25-4).

the mouth of the inferior caval vein by an additional folding, called the sinus septum. The tendon of Todaro, one of the important landmarks of the triangle of Koch, runs through this area to insert into the central fibrous body (see Fig. 25-3). The remainder of the antero-inferior rim

Figure 25-3 The heart shown in Figure 25-2 has been reconstituted, and sectioned through the oval fossa in four-chamber fashion, but photographed so as to show the anterior parts. Note that the alleged septum secundum is no more than an infolding between the opening of the superior caval vein (SCV) to the right atrium and the right upper pulmonary vein to the left atrium. Note also the course of the tendon of Todaro (black dotted line), the continuation of the Eustachian, which guards the mouth of the inferior caval vein (ICV). The atrial wall beyond the tendon (star) is the vestibular component of the atrioventricular muscular sandwich.

is another true septal structure, produced by muscularisation of the developmental component known as the vestibular spine (see below). The right atrial wall continues beyond this septal component, inserting into the vestibule of the tricuspid valve, and forming the atrial component of the muscular atrioventricular sandwich (see Fig. 25-3; see also Chapter 27). As explained in Chapter 2, this region is a sandwich rather than a true septum. This is because an extension of the inferior atrioventricular groove produces a fibroadipose layer between the sheet of atrial musculature and the underlying ventricular mass. It is only the thin translucent floor of the oval fossa, formed from the primary atrial septum, together with the antero-inferior muscular rim of the fossa, which are true interatrial septal structures. As such, they can be removed without exiting from the cavities of the heart (Fig. 25-4). When viewed from the left atrial aspect, the morphology is less complex. The floor of the fossa is smooth, but in its anterosuperior margin it is roughened and wrinkled, forming two horns where it overlaps the infolded superior interatrial groove. In the majority of normal individuals, the flap valve and rim are fused, but as emphasised, anatomical fusion does not occur in about one-third of the population, and the heart shown in Figure 25-5 has probe patency of the oval foramen (Fig. 25-6).

Types of Interatrial Communication

It is on the basis of this septal morphology that we should distinguish between the different anatomical types of interatrial communications, and recognise that not all are deficiencies of the septal components. Holes between the atria can be divided into the so-called primum and

Figure 25-4 The cartoon illustrating the structure of the septal components (A) shows how it is possible to remove the floor of the oval fossa (B) and stay within the heart, whereas removing the superior rim (C) takes the prosector into the pericardial cavity.

Figure 25-5 When viewed from the left atrium, the flap valve of the oval fossa in the usual situation overlaps the infolded superior rim. The stars show the attachment of the horns of the flap valve on the left atrial aspect of the oval fossa.

secundum types, to which need to be added the sinus venosus defects, those found at the site of the mouth of the coronary sinus, and the rare vestibular defect (Fig. 25-7).

Of these various lesions, it is the alleged secundum defects that are within the confines of the oval fossa, and

Figure 25-6 In the heart shown in Figure 25-5, as demonstrated by passing a probe up the inferior caval vein, although the floor of the fossa overlaps its rim on the left atrial aspect, the two components are not fused one to the other. This is probe patency of the oval foramen, and is found in about one-third of the normal population.

Figure 25-7 The cartoon shows the various types of interatrial communication. Only the defects within the oval fossa, and the rare vestibular defects, are produced by true deficiencies of the septal components.

hence, along with the vestibular defect,¹³ those which represent true deficiencies of the atrial septum. The so-called secundum defects result from deficiency of the primary atrial septum, which forms the floor of the oval fossa. The vestibular defect occurs because of inappropriate muscularisation of the vestibular spine and the mesenchymal cap that clothes the leading edge of the primary septum during cardiac development (see Chapter 3). The

other defects do unequivocally permit interatrial shunting, and so, with the exception of the primum defect, they are rightly considered in this chapter. They are, nonetheless, more accurately described as interatrial communications.

The so-called ostium primum defect is an atrioventricular septal defect found in the setting of a common atrioventricular junction, but in which the fused bridging leaflets of the common atrioventricular valve are also fused to the scooped-out crest of the ventricular septum. Because of this, shunting across the atrioventricular septal defect occurs only at atrial level. This defect is considered in Chapter 27. The sinus venosus defects are found in the mouths of the caval veins, most usually the superior caval vein, but also in the mouth of the inferior caval vein. The phenotypic feature of these defects is that the oval fossa itself is intact, or else its floor is deficient.¹⁴⁻¹⁶ These defects exist because of anomalous attachment of one or other of the right pulmonary veins. The coronary sinus defect is at the mouth of the coronary sinus.¹⁷ It permits interatrial shunting because of fenestration of the walls which normally separate the coronary sinus and the left atrium. This type of defect is almost always associated with drainage of the left superior caval vein to the roof of the left atrium. The rare vestibular defect is another true septal defect, which is found when the components forming the antero-inferior rim of the fossa do not muscularise appropriately during cardiac development.¹³ On the basis of this introduction, we will now describe these defects in more detail.

Defects Within the Oval Fossa

These defects are by far the most common type of interatrial communication, and are true atrial septal defects. Although usually termed secundum defects, this term is justified only because the defect is present at the site of the secondary embryonic foramen, and not because there is inappropriate formation of the so-called septum secundum. As we have emphasised, this alleged septum is no more than a deep fold between the attachments of the superior caval vein to the right atrium, and the right pulmonary veins to the left atrium (see Fig. 25-3). The defects found within the oval fossa result from deficiency, perforation, or complete absence of its floor, which is derived from the primary embryonic septum. As we have also emphasised, the upper border of the primary septum fails to fuse with the left atrial aspect of the infolded superior rim of the oval fossa in around one-third of normal individuals, even though it overlaps the rim (see Fig. 25-6). This is probe patency of the oval foramen. As long as left atrial pressure is higher than right, which is the normal situation, such a happening does not permit interatrial shunting under ordinary circumstances. Probe patency, nonetheless, is known to be responsible for paradoxical embolism, and can be an important finding in those undertaking deep sea diving. The finding has also been implicated recently as a cause of some cases of migraine,⁶ and for this reason there has been a vogue for closing such probe-patent foramina by non-surgical means. When measuring such foramina, it should be remembered that the potential hole is a tunnel between the edge of the flap valve and the infolded superior rim of the fossa, rather than being a hole with dimensions that can be measured as occurs for the true septal deficiencies. There is a spectrum of size for defects within the oval fossa, depending on the degree of deficiency of the primary septum. The least severe type of defect is found when the flap valve is minimally

deficient, so that it fails to overlap entirely the left atrial margin of the rim of the fossa. With increasing deficiency of the flap valve (Fig. 25-8), the defect becomes larger. In extreme cases there may be no floor to the fossa (Fig. 25-9). Alternatively, the flap valve may be perforated, with either single or multiple perforations (Fig. 25-10). When the deficiency is marked, the hole can extend towards the mouth of the inferior caval vein, which may then straddle the

Figure 25-8 In this instance, about half of the floor of the fossa is deficient, producing a defect of significant size.

Figure 25-9 In this patient, the floor of the oval fossa is totally deficient, but there is preservation of the antero-inferior rim. Note the extension of the defect towards the inferior caval vein (ICV). (Courtesy of Dr Benson R. Wilcox, University of North Carolina, Chapel Hill.)

persisting rim to open in part to the left atrium. In the most extreme form of septal deficiency, the hole can extend from the openings of the caval veins and coronary sinus to the septal attachment of the tricuspid valve, but still with a muscular infero-anterior rim separating the right and left atrioventricular junctions. This arrangement should be distinguished from an atrioventricular septal defect with common atrioventricular junction and virtually absent atrial septum. In addition to the small rim of antero-inferior musculature persisting when the defect is due to absence of the floor of the oval fossa, the atrioventricular valvar morphology will distinguish the two types. When the defect is within the oval fossa, the left atrioventricular valve has the characteristic morphology of the mitral valve, whereas when there is a common atrioventricular junction, it has the anticipated trifoliate arrangement (see Chapter 27).

When defects are present within the confines of the fossa, they do not alter the basic disposition of either the sinus or atrioventricular nodes. When the inferior rim is effaced, the node will of necessity be confined to the narrow strip of myocardium between the edge of the defect and the septal attachment of the tricuspid valve. This will still be within the triangle of Koch, readily visible in Figures 25-9 and 25-10, but the triangle itself will be narrow. Apart from this circumstance, the morphology of the atrioventricular junctional area will be normal in the presence of septal defects within the oval fossa. Although these defects may exist in isolation, they often occur in combination with many other congenital cardiac malformations.

Sinus Venosus Defects

The essence of the so-called sinus venosus defects is that they exist outside the confines of the oval fossa.¹⁴⁻¹⁶ The defects are usually found in the mouth of the superior caval vein, but can also be found at the orifice of the inferior

Figure 25-11 The cartoon shows the phenotypic feature of the superior sinus venosus defect, namely an extracardiac conduit created by anomalous connection of the right pulmonary veins at the superior cavoatrial junction. SCV, superior caval vein.

caval vein (see Fig. 25-7). In the case of the superior sinus venosus defect, the orifice of the superior caval vein typically overrides a defect, which has the superior rim of the fossa as its floor. The phenotypic feature of the defect is anomalous insertion of right pulmonary veins into the wall of the superior caval vein, which creates the conduit through which the blood can shunt between the atrial chambers (Fig. 25-11). Indeed, we have now encountered a heart with such a defect in which there is no overriding of the orifice of the superior caval vein. Despite the normal attachment of the caval vein to the right atrium, the anomalous attachment of the right pulmonary veins still create the interatrial communication outside the confines of the intact atrial septum (Fig. 25-12). In most instances, nonetheless, as seen in the specimen shown in Figure 25-13, the defect has a well-circumscribed inferior margin, the superior rim of the oval fossa, but does not have a roof. In these more usual circumstances, the superior caval vein is attached in part to the right atrial wall and in part to the left atrial myocardium (see Fig. 25-13). Usually, the lower right pulmonary vein inserts into the left atrial wall, the middle pulmonary lobe vein drains into the area of the defect, and the upper right pulmonary vein drains directly into the superior caval vein. In this setting, the superior rim of the fossa becomes a muscular tube enclosing a corridor of extracardiac fat. A probe can be passed from back to front through the tube without encroaching on the atrial cavities (see Fig. 25-13). The presence of a superior sinus venosus defect does not markedly affect the site of the sinus node, which is found lateral to the superior cavoatrial junction, lying immediately subepicardially within the terminal groove. Thus, a patch placed within the atrium to reconnect the caval vein to the right side should not jeopardise the sinus node. Because of the usual overriding of the superior caval vein, and the usual presence of anomalous pulmonary veins, it may not be possible to septate the defect in such a way that normal pulmonary venous return is restored without narrowing the superior caval pathway. In these circumstances, it may be difficult to widen the caval vein without putting either the sinus node or its vascular supply at risk, since the artery to the node may pass either in front of or behind the cavoatrial

Figure 25-12 In this specimen, the superior caval vein (SCV) is normally attached within the right atrium, but the anomalous attachment of the right upper pulmonary veins creates a superior sinus venosus defect well removed from the margins of the oval fossa.

Figure 25-13 In the more usual type of superior sinus venosus defect (compare with Fig. 25-12), the mouth of the superior caval vein (SCV) overrides the intact superior rim of the oval fossa, which encloses a corridor of extracardiac fat, through which the probe has been placed from the back to the front of the heart.

junction to enter the node. Despite this caveat, most defects can be closed without jeopardising normal function of the node. Inferior sinus venosus defects are far less common.¹⁶ They, too, are associated with an anomalous attachment of the right pulmonary veins, but in these cases, it is the

Figure 25-14 An inferior sinus venosus defect is shown from its right atrial aspect in a heart with an intact oval fossa and a persistent left superior caval vein draining through the enlarged opening of the coronary sinus. Note that the inferior caval vein is attached in normal fashion to the right atrium, with the defect produced by anomalous attachment of the right inferior pulmonary vein.

anomalous attachment of the right inferior pulmonary vein that creates the extracardiac conduit (Figs. 25-14). Closure of such a defect should not jeopardise either the sinus or the atrioventricular node. Inferior sinus venosus defects must, of course, be distinguished from defects within the oval fossa which extend towards the mouth of the inferior caval vein (see Fig. 25-9).

Coronary Sinus Defects

The coronary sinus defect consists of an interatrial communication through the orifice of the coronary sinus, with absence of the usually adjacent walls of the coronary sinus and left atrium. Most times there is also connection of a persistent left superior caval vein to the left atrial roof.¹⁷ In essence, the anomaly is the consequence of absence of the walls which normally exist between the coronary sinus and the left atrium. In their absence, the orifice of the coronary sinus becomes an interatrial communication (Fig. 25-15). In some examples of this combination, filigreed remnants of the atrial wall persist between the orifice of the coronary sinus and the termination of the left caval vein in the left atrium. More commonly, as shown in Figure 25-15, there is no tissue separating the coronary sinus, the mouth of the left caval vein, and the cavity of the left atrium. The opening of the coronary sinus is usually large. When such a defect is large, its anterior margin encroaches on the triangle of Koch, approximating the area of the atrioventricular node. Care must be taken, therefore, when the defect is closed. In this respect, unless previously diagnosed, a coronary sinus defect may be difficult to recognise as an interatrial communication in the operating room, appearing simply to be the mouth of the coronary sinus itself.

The Vestibular Defect

The heart shown in Figure 25-16 has a defect in the antero-inferior margin of the oval fossa. The fossa itself exhibits two additional defects, and the tricuspid valve is hypoplastic, since the patient also had pulmonary atresia in the setting

Figure 25-15 In this heart, absence of the walls that normally separate the coronary sinus from the left atrium have left the mouth of the sinus to function as an interatrial communication. SCV, superior caval vein.

Figure 25-16 The heart has a septal deficiency in the antero-inferior margin of the oval fossa, this being the part derived by muscularisation of the vestibular spine.¹³ (Courtesy of Dr Geoffrey Sharratt, Halifax, Nova Scotia, Canada.)

of an intact atrial septum. This lesion is a true atrial septal defect through the septal component of the muscular margin of the oval fossa.¹³

Morphogenesis of Interatrial Communications

During normal development, the embryonic primary septum grows down to divide the primary atrium, carrying with it a cap of mesenchymal tissue (Figs. 25-17 and 25-18, upper panels). This cap will fuse with the atrioventricular

Figure 25-17 The panels show the sequence of formation of the normal atrial septum as seen in the four-chamber orientation.

Figure 25-18 The panels show the same sequence of events as shown in Figure 25-17, but as seen from the right side.

endocardial cushions, and will then be reinforced by the vestibular spine to close the primary interatrial foramen (see Figs. 25-17 and 25-18, middle panels). As its lower edge fuses with the cushions, its top edge breaks down to form the secondary foramen (see Fig. 25-18, middle panel). The upper edge of the remaining primary atrial septum is then usually overlapped by the infolding of the atrial roof

between the superior caval and pulmonary veins, this fold forming the superior rim of the oval fossa, often described as the septum secundum (see Figs. 25-17 and 25-18, lower panels).

Failure of normal development of the atrioventricular junction prevents the lower edge of the primary septum from fusing with the ventricular septum. This results in the so-called ostium primum defect, which is an atrioventricular septal defect with common atrioventricular junction, and is described further in Chapter 27. It is maldevelopment of the primary atrial septum itself, after it has fused with the ventricular septum and the endocardial cushions, which results in defects within the oval fossa. This can either be due to deficiency of its superior edge, so that it no longer overlaps the infolded superior rim, or breakdown of the septum to a greater or lesser degree, resulting in the various types of perforate or fenestrated defects within the fossa (see Fig. 25-10). In the most severe defects, the muscular rim also becomes effaced. It is possible to envisage temporary effacement of the rim of the oval fossa, since this is no more than a muscular infolding. Such effacement in the presence of volume load, with subsequent restoration of the fold once the volume load has been corrected, is a likely explanation for so-called spontaneous closure of some defects within the oval fossa during the neonatal period. Sinus venosus defects are best explained on the basis that the right pulmonary veins are abnormally attached to the wall of either the superior or inferior caval veins (see Figs. 25-12 and 25-14). Resorption of the walls normally formed between the pulmonary and caval veins will produce a defect outside the margins of the oval fossa, usually also permitting biatrial communication of the caval vein itself. The coronary sinus defect is best explained on the basis of similar resorption of the walls which usually separate the lumen of the coronary sinus from the cavity of the left atrium (see Fig. 25-15). The rare vestibular defect (see Fig. 25-16) is likely due to improper muscularisation of the antero-inferior rim of the oval fossa, this usually requiring involvement of both the vestibular spine and the mesenchymal cap carried on the leading edge of the atrial septum.¹³

Associated Anomalies

Cardiac

Certain cardiac and vascular anomalies have been reported to occur more frequently in patients with an atrial septal defect than in the general population. The atrioventricular valve is essentially a common structure in the setting of an atrioventricular septal defect with common atrioventricular junction but with shunting confined at atrial level, the so-called ostium primum defect, as considered in Chapter 27. Hence, it is inappropriate always to consider such valves as abnormal, albeit that they often show additional malformations. Such additional malformations are less common with other varieties of interatrial communication, but do occur. A prolapsing mitral valve, for instance, was found in one-sixth of one series of patients.¹⁸ The incidence amongst the patients undergoing surgical closure in Pittsburgh was only 2.5%. The true incidence is hard to determine, since the criteria for diagnosing prolapse are different in different institutions.

Anomalous connection of the pulmonary veins is a relatively common associated finding in patients with interatrial

communications. Indeed, it is the phenotypic feature of the sinus venosus variety. This feature was reported in one-sixth of the patients undergoing surgery at Pittsburgh, but was seen in five-sixths of those said to have sinus venosus defects, compared to only 1.7% of those with a defect within the oval fossa. This statistic, however, calls into question the nature of those patients allegedly having a sinus venosus defect in the absence of anomalous connection of the pulmonary veins. It is very likely that re-examination of these patients would reveal that initially they had oval fossa defects extending towards the openings of the caval veins.

An interatrial communication may co-exist with a ventricular septal defect, persistent patency of the arterial duct, or coarctation of the aorta. The true incidence is hard to determine, since each of these defects may lead to increased left atrial pressure and size, while the interatrial communication may be due to incompetence of a stretched oval foramen. Although a small gradient across the right ventricular outflow tract is common in patients with an interatrial communication, such stenosis is usually functional, and related to increased flow. Organic pulmonary stenosis requiring surgical attention was uncommon in the series of patients undergoing surgery in Pittsburgh, occurring in less than one-twentieth.

Non-cardiac

The association of Down's syndrome with ostium primum defects is well known. It occurred in three-tenths of patients undergoing surgery for such defects in Pittsburgh. The incidence of Down's syndrome was only 2.9% in those having surgery for atrial septal defect in the oval fossa. The skeletal anomalies of the Holt-Oram syndrome,¹⁰ and electrophysiological abnormalities,¹² are examples of non-cardiac anomalies, which occur in a few patients. As with associated cardiac malformations, non-cardiac anomalies are relatively rare in patients with an atrial septal defect.

PATHOPHYSIOLOGY

The pathophysiology of an atrial septal defect is related to the magnitude and direction of shunting of blood across the interatrial communication. There is usually a substantial left-to-right shunt, resulting in a high ratio of pulmonary to systemic flow. The primary determinants of the amount of shunting are the size of the defect and the relative resistance to inflow, or the compliance, of the ventricles. The latter factor is greatly influenced by pulmonary vascular resistance. The compliance of the right and left atriums themselves may also play a role, but this has been difficult to prove. As with a ventricular septal defect, the site of the defect in the atrial septum does not influence the magnitude of flow across it, although relative contributions to the shunt from the individual pulmonary veins do vary depending on the location of the defect.

Effect of Size of the Defect

The size of the interatrial communication is an important determinant of the magnitude of the shunt. Because of the lower resistances involved, an interatrial communication tends to be larger than a ventricular defect for a shunt of similar magnitude. Most interatrial communications recognised clinically are essentially non-restrictive, and approximate the area of the mitral valvar orifice. The defect

imposes no more restriction to flow across it than does the mitral valve. There is, therefore, at most a small pressure gradient between the atriums. If the defect is smaller and restrictive, the flow of blood to the lungs will be limited by the size of the defect. The ratio of flows usually will be less than 2 to 1. There is no doubt that many small defects escape clinical detection because a limited left-to-right shunt is haemodynamically well tolerated, and causes no abnormalities in the physical examination.

In some cases, the interatrial communication may result from incompetence of the valve of the oval foramen, rather than a true deficiency of the atrial septum. This incompetence can lead to considerable left-to-right shunting when there are associated abnormalities that lead to increased left atrial pressure. Mitral stenosis, a dysfunctional left ventricle, aortic stenosis, coarctation of the aorta, systemic hypertension, patency of the arterial duct, and ventricular septal defect are examples. If the primary defect leading to volume or pressure overload of the left atrium can be corrected, the valve may become competent and the atrial shunt will then disappear. Some otherwise normal infants have left-to-right atrial shunting owing to transient incompetence of the valve of the oval foramen. This phenomenon was well described,¹⁸ and subsequently confirmed by the widespread use of Doppler echocardiography in newborns and young infants. It is likely to be caused by effacement of the superior infolded rim.

Effect of Ventricular Compliance

If the atrial defect is non-restrictive, the magnitude of the shunt will be directly related to the relative resistance to filling offered by the right and left ventricles. The inflow resistance of a ventricle, or its compliance, is related to its diastolic function and distensibility. This is largely related to its mass, but other factors may also play a role in the complex determination of diastolic function. The mass, and hence the compliance, of the right ventricle is influenced by pulmonary vascular resistance. It undergoes predictable postnatal changes. At birth, right and left ventricular compliances are approximately equal, and there is little shunting across an atrial defect in either direction. Pulmonary vascular resistance and pressure generally undergo their normal dramatic fall over the first days of life in patients with an interatrial communication. This is true even in a patient with a large defect, since the pulmonary vascular bed is never exposed to systemic arterial pressure, as it is with a large ventricular septal defect or aortopulmonary communication. It takes several months, however, before the mass of the right ventricle decreases relative to that of the left ventricle. Only then is a normal adult relationship reached between the two ventricles. Hence, a significant left-to-right shunt is not expected until several months of age. Pulmonary arterial pressure at this stage is almost always normal. Although patients with an atrial septal defect have a normal regression of pulmonary vascular resistance, they are susceptible to a secondary increase in resistance if the flow of blood to the lungs remains high for many years, usually several decades.^{3,18,19} As pulmonary vascular resistance rises, the pulmonary arterial pressure also increases. This causes right ventricular hypertrophy with a concomitant decrease in compliance, which leads to less left-to-right shunting. As right ventricular compliance

approaches that of the left ventricle, there is little shunting across the defect. If right ventricular compliance exceeds that of the left ventricle, there will be a right-to-left atrial shunt, since the atriums will empty preferentially into the more easily filled left ventricle. If there is associated severe pulmonary stenosis, hypertrophy of the right ventricle will occur. The resulting decreasing compliance of this chamber may eventually lead to right-to-left shunting. A right-to-left atrial shunt may also be caused by tricuspid stenosis or severe tricuspid valvar regurgitation. In addition to changes in right ventricular compliance, abnormal filling characteristics of the left ventricle can also influence the magnitude of the atrial shunt. Filling of the left ventricle is impaired by mitral stenosis, or by any abnormality that leads to increased diastolic pressures in the left ventricle. This may result in marked accentuation of the left-to-right shunt across the atrial defect.

Cardiac Response to the Interatrial Communication

The usual haemodynamic characteristics of an uncomplicated interatrial communication are a large left-to-right shunt and normal pulmonary arterial pressure. Flow across the defect is phasic, and occurs predominantly in late ventricular systole and early diastole.²⁰ Numerous studies have documented that most patients with a typical defect within the oval fossa have a small right-to-left shunt. It occurs mainly from streaming of a portion of the return from the inferior caval vein directly across the defect into the left atrium.^{19,21} This small shunt is not detectable by oximetry, so there is no systemic desaturation, but it can be demonstrated by indicator dilution techniques,²² contrast echocardiography,²³ and Doppler studies.²⁴

The contribution of the pulmonary venous return from each lung to the total left-to-right shunt is unequal. In a typical large defect, four-fifths of the pulmonary venous return from the right lung shunts left to right. This is in contrast to between one-fifth and two-fifths of the pulmonary venous return from the left lung.^{18,19,22} In a sinus venosus defect, it is the anomalously connected right pulmonary veins that provide most of the shunted blood. This preferential shunting from the right lung does not occur to any great extent with an ostium primum interatrial communication.

A large left-to-right shunt at the atrial level leads to enlargement of both the right atrium and the right ventricle.²⁵ The left atrium is of normal size despite the increased pulmonary venous return, since the atrial septal defect allows its decompression. Left ventricular dimensions are usually normal, although some studies have shown left ventricular end-diastolic volume to be less than normal.²⁶

Systemic cardiac output is almost always normal in children. Exercise tolerance is good, probably because the cardiovascular response to exercise favours a decrease in the magnitude of the atrial shunting. The afterload on the left ventricle is decreased by the drop in systemic vascular resistance that attends exercise, tending to facilitate left ventricular filling. The increased cardiac output also augments systemic venous return, competitively filling the right atrium at the expense of shunting across the defect. In contrast to the situation in childhood, systemic cardiac output has been found to be decreased in up to half the patients with an atrial septal defect who are older than 18 years of

age.²⁷ Numerous studies in adults have shown significant left ventricular dysfunction, which may persist even after surgical correction.^{26,28,29}

Despite the greatly increased flow of blood to the lungs, pulmonary arterial pressure is rarely elevated in children, and pulmonary vascular resistance is low, frequently less than 1 Wood unit.³⁰ The incidence of pulmonary hypertension in children less than 20 years of age is no more than one-twentieth in most studies but increases to one-fifth of those aged from 20 to 40 years, and is found in half of the patients older than 40 years.^{3,19,31,32} The incidence of elevated pulmonary vascular resistance also increases with age.^{27,33} Severe elevation of resistance, and Eisenmenger's reaction, however, is unusual, occurring in only about one-twentieth of patients.^{34,35} With severe elevation of pulmonary vascular resistance, right ventricular hypertrophy may increase, and compliance decrease, sufficiently that cyanosis results from reversal of the atrial shunt. This suggests slowly progressive development of pulmonary vascular disease, presumably resulting from increased flow of blood to the lungs over many years. Heath and Edwards³⁶ described changes in the pulmonary vascular bed consistent with this hypothesis, including a predominance of intimal fibrosis and endothelial proliferation, but with less medial muscular hypertrophy than is seen in patients with ventricular septal defects. There are many aspects of the clinical spectrum that are not explained by this simplistic scheme. On the one hand, although it is uncommon, some children with isolated atrial septal defects do have pulmonary hypertension. On the other hand, there are adults who live into their sixth and seventh decades with markedly increased flow to the lungs who have normal pulmonary vascular resistance and normal pulmonary arterial pressure.^{27,37} There must, therefore, be individual variation of pulmonary vascular reactivity to various noxious stimuli such as increased pulmonary flow, increased pressure, and so on. As yet, these features are poorly understood.

The chronic right ventricular volume overload caused by an interatrial communication is generally well tolerated for many years, particularly when there is no associated elevation of pulmonary arterial pressure. Congestive heart failure rarely occurs before the fourth or fifth decades but has been reported to be present in approximately one-third of patients greater than 40 years of age.^{27,33} Rarely, an isolated defect may cause congestive heart failure in infancy.^{38–40} Another cardiac consequence of the long-standing left-to-right shunt is the occurrence of atrial arrhythmias, particularly atrial flutter and fibrillation. They presumably result from chronic stretching of the atriums, and occur most commonly in patients greater than 40 years of age.^{37,41,42} As with the other complications associated with inter-atrial communications, atrial arrhythmias rarely occur in childhood. Electrophysiological studies, nonetheless, have demonstrated a high incidence of subclinical dysfunction of the sinus node, along with conduction disturbances, in children prior to operative intervention.^{43–46}

CLINICAL FINDINGS

Presentation

Mild dyspnoea on exertion, and/or easy fatiguability, are the most common early symptoms of an interatrial communication. They are not usually present during infancy

and childhood, or may be appreciated only in retrospect after a diagnosis has been made. Not infrequently, parents report increased activity and vigour after repair, even though they had considered their child to be asymptomatic prior to surgery. Infants less than 1 year of age may rarely present with congestive heart failure owing to an isolated defect. Some children have an increased number of respiratory infections. Additionally, some infants who are predisposed to respiratory compromise, such as those with bronchopulmonary dysplasia, may suffer more significant effects from the atrial shunting, and may benefit from early closure of the defect. Symptoms become much more common in the fourth or fifth decades, for reasons already discussed. Some patients, even with a large defect, may be in their sixth or seventh decades before they demonstrate dyspnoea on exertion, easy fatigue, or frank congestive heart failure. A few remain free of disabling symptoms throughout life.

Physical Examination

The general physical examination is usually normal, although there is a tendency toward a slender physique (Fig. 25-19). Associated non-cardiac abnormalities are uncommon in individuals with a defect within the oval fossa or a sinus venosus defect.⁸ Skeletal anomalies of the forearm and hand do occur occasionally, and this syndrome may be inherited.¹⁰ Non-cardiac anomalies much more commonly accompany ostium primum defects. Notable examples include Down's syndrome⁴⁷ and the visceral anomalies typically present with isomerism of the atrial appendages.⁴⁸

The jugular venous pulse is usually normal, as are blood pressure and peripheral arterial pulses. A left parasternal lift is often present, but precordial motion is normal in some patients, especially if the left-to-right shunt is not large. Rarely, there is asymmetric development of the chest with a protuberance of the lower left aspect of the thorax. Cyanosis is not part of the clinical picture of an uncomplicated interatrial communication. It can occur under certain circumstances, for example with virtual absence of the interatrial septum or when there is anomalous systemic venous connection to the left atrium.

The heart sounds are almost always abnormal. It is difficult to entertain making the diagnosis clinically when

auscultation is completely normal. The first sound at the low left sternal border is usually accentuated because of prominent closure of the tricuspid valve.⁴⁹ The increased diastolic flow across the tricuspid valve tends to keep the leaflets widely open until ventricular systole begins. The wider excursion of the leaflets prior to coaptation may, therefore, explain the loudness of the closure. Alternatively, the wide-open position of the leaflets may result in closure that is slightly late. As a result, closure occurs during the more steeply rising portion of the ventricular pressure curve and causes a more forceful coaptation. The second sound is characteristically widely and fixedly split, with little or no variation in the width of the split during the respiratory cycle. Fixed splitting may be appreciated during quiet respiration, or by listening during held expiration. The latter technique has the advantage of eliminating breath sounds during auscultation and is probably the more sensitive method. If an individual with a normal heart is asked to breathe all the way out, and then stop breathing, the second sound will be single for one to three beats. It will then become split, the splitting gradually widening over the next several beats (Fig. 25-20A). In contrast, the second sound of a patient with an atrial septal defect is split at the end of expiration. The degree of splitting then varies little or not at all during held expiration (see Fig. 25-20B).

The normal inspiratory exaggeration of splitting is supposedly related to the augmentation of systemic venous return induced by the negative intrathoracic pressure of inspiration. The increased right ventricular filling prolongs ejection, leading to a delayed closure of the pulmonary valve, which is then separated from the sound of aortic closure. Several reasons for the lack of respiratory variation in splitting in patients with an interatrial communication have been suggested. The most widely accepted explanation postulates a reciprocal relationship of changes in pulmonary and systemic venous return with respiration.⁵⁰ An alternative explanation relates the delayed closure to a separation of the right ventricular and pulmonary arterial pressure curves rather than to prolongation of ventricular systole, which rarely occurs. The pulmonary arterial curve is typically delayed, and the dip, corresponding to pulmonary valvar closure, hangs out beyond the descending ventricular pressure curve.⁵¹ Whatever the true genesis of fixed splitting, it is a most valuable sign of a large left-to-right shunt at the atrial level.

The murmurs associated with an atrial septal defect are typically soft. They may be absent in infancy and early childhood, explaining the relative lateness of diagnosis in most individuals. It is extremely uncommon for a murmur to arise at the site of the interatrial communication itself, since there is usually little or no gradient across it. Instead, the murmurs are generated by rapid blood flow through the right heart and the pulmonary arterial bed. Almost all individuals with a clinically recognisable atrial septal defect have a crescendo-decrescendo systolic murmur at the high left sternal border. This is related to rapid flow across the pulmonary valve. The murmur is usually soft, and a murmur of greater than grade 3 to 6 should suggest the possibility of accompanying pulmonary stenosis. It is easy to overestimate the severity of obstruction within the right ventricular outflow tract. Even a loud systolic murmur may be generated at a very mildly stenotic pulmonary valve. A similar systolic murmur is usually audible in the axillas

Figure 25-19 The centiles for weight of patients undergoing surgical repair of an atrial septal defect at the Children's Hospital of Pittsburgh. The normal distribution of weight is indicated by the solid line, and that in the patients by the bars. The distribution is skewed in the patients toward the lower percentiles.

Figure 25-20 This phonocardiogram was recorded at the high left sternal border during held expiration. Respiration is indicated by the solid line. **A**, Normal splitting. The second heart sound is single on the first beat, while subsequent beats show gradually increasing splitting. **B**, Fixed splitting. The second heart sound is split on the first beat, and there is only trivial widening of the split with subsequent beats. and over the posterior thorax. It is generated by rapid flow of blood through the pulmonary arteries.

Most individuals with a large left-to-right shunt through an interatrial communication also have a soft mid-diastolic murmur at the low left sternal border. This murmur is always subtle and is almost never recognised unless specifically listened for. The murmur is that of relative tricuspid stenosis, and is generated by rapid flow across a normal tricuspid valve. Unlike the murmur of organic or relative mitral stenosis, the murmur is not low pitched and rumbling. Rather, it is of medium pitch and is often scratchy. There is always an audible gap between the second heart sound and the murmur. None of the murmurs associated with an interatrial communication are affected significantly by the phase of respiration or by position. Although the murmurs just described arise at a distance from the defect, under certain circumstances a murmur may be generated at the defect itself. The prerequisite is a relatively large gradient between the atria. Such a gradient occurs only if the defect is small and restrictive and if left atrial pressure is higher than normal, usually because of mitral stenosis⁵²

or mitral atresia.⁵³ The murmur is continuous, since under these circumstances, left atrial pressure exceeds right atrial pressure throughout the cardiac cycle. The murmur is usually soft and maximal near the lower sternum. Rarely, the murmur is loud with an accompanying thrill and may have a roaring quality.

The physical findings associated with an interatrial communication are greatly altered by the appearance of pulmonary vascular disease. With an increase in right ventricular pressure, the left parasternal lift may become more pronounced. An elevation of pulmonary arterial pressure tends to close the pulmonary valve earlier as the typical loose system of an uncomplicated atrial defect becomes more tight. The interval of hang out then decreases. The elevated pulmonary arterial diastolic pressure also contributes to earlier pulmonary closure. The second heart sound, therefore, becomes narrowly split, or single, as long as right ventricular function is not severely impaired. If right ventricular contractility is sufficiently diminished, pulmonary valvar closure will be delayed by a prolonged ejection time, and the second heart sound will again become

Figure 25-21 Surface electrocardiogram from a child with an atrial septal defect within the oval fossa. There is right-axis deviation and mild right ventricular hypertrophy manifested by an RSR' pattern in the right precordial leads.

widely split. Splitting of the second heart sound in an individual with an atrial septal defect and pulmonary hypertension, therefore, depends on right ventricular function. It is narrow or absent as long as right ventricular function is normal; it is wide if right ventricular function is compromised. With an increase in pulmonary vascular resistance, there is a decrease in the flow of blood to the lungs. The systolic and diastolic murmurs associated with rapid flow of blood through the right heart and pulmonary arteries then disappear. If pulmonary hypertension is severe, new murmurs of pulmonary and tricuspid regurgitation may occur. The murmur of hypertensive pulmonary regurgitation is typically high pitched and decrescendo, being maximal at the high and mid-left sternal border. This murmur is usually clinically indistinguishable from the murmur of aortic regurgitation unless the second heart sound is widely split, and it can be appreciated that the diastolic murmur begins with the second pulmonary component. The murmur of tricuspid regurgitation is high pitched and systolic; it is usually maximal at the low left sternal border. It may be either early or pansystolic, and it may increase in intensity with inspiration, a feature known as Carvallo's sign.⁵⁴

INVESTIGATIONS

Electrocardiography

The electrocardiographic features of an interatrial communication are stereotyped in childhood (Fig. 25-21). Similar findings may be present, nonetheless, in normal children or in individuals with other conditions that cause right ventricular volume overload. Normal sinus rhythm is the rule in childhood, but atrial flutter or fibrillation is seen with increasing frequency after 40 years of age.

First-degree atrioventricular block has been reported to occur in up to one-third of patients.^{3,30} In contrast to this high reported prevalence, this finding was present in only 4% of the patients with defects within the oval fossa seen at the Children's Hospital of Pittsburgh. The morphology of the P wave is normal in such defects, but one review demonstrated that, in nearly half of sinus venosus defects, the frontal plane axis of the P wave was less than 15 degrees, suggesting a low atrial focus.⁵⁵ In Pittsburgh, however, a definite ectopic atrial rhythm was seen in only 7% of patients with sinus venosus defects. In children with deficient atrial septation, the frontal plane QRS axis is almost always in the range from 90 degrees to 170 degrees, but in the adult the axis may shift leftward to the range of 70 degrees to 90 degrees. Although left-axis deviation occurring in the setting of an atrial shunt strongly suggests the presence of an ostium primum defect, approximately one-twentieth of those with oval fossa and sinus venosus defects have this axis.^{30,55} Mild-to-moderate right ventricular hypertrophy is present in more than five-sixths of patients, and is usually manifested by an RSR' pattern in the right precordial leads. The R or R' wave rarely exceeds 15 mm unless there is significant elevation of pulmonary vascular resistance and pulmonary arterial pressure.^{18,33} The QRS duration is either normal or mildly prolonged, rarely exceeding 0.11 second. Complete right bundle branch block is very rare in childhood, but occurs in nearly half of patients older than 60 years of age.³⁷

Radiology

The chest radiograph shows mild-to-moderate cardiomegaly in most patients, but up to one-sixth of patients have a heart of normal size, even in the presence of a

large left-to-right shunt.^{33,56} Irrespective of whether or not the heart is enlarged, there is almost always an abnormal contour, with a large right atrium, right ventricle, and pulmonary trunk and a diminutive aorta (Fig. 25-22). Pulmonary vascular markings are usually increased when the ratio of pulmonary to systemic flow is 2 to 1 or greater, but the vascularity correlates poorly with the magnitude of the shunt.⁵⁷ Once pulmonary vascular disease develops,

the typical findings of Eisenmenger's syndrome may be present, with aneurysmal dilation of the proximal pulmonary arteries and distal tapering of the vessels. In patients with a sinus venosus defect, there may be localised dilation of the proximal superior caval vein at the entrance of the anomalous pulmonary veins, giving the appearance of a higher than normal vascular pedicle in the right hilum. In most patients with this type of defect, however,

Figure 25-22 Chest radiographs and barium swallow in a patient with an atrial septal defect. A, Frontal view shows cardiomegaly and increased pulmonary vascular markings. The pulmonary trunk is large, and the aortic knob is not apparent. B, Lateral view shows that there is no oesophageal deviation to suggest left atrial enlargement. C, Right anterior oblique view confirms the absence of left atrial enlargement, but the cardiac shadow approaches the left thoracic wall, suggesting right ventricular enlargement. D, Left anterior oblique view.

the radiological findings are identical to those of a typical defect within the oval fossa.

Echocardiography

Echocardiography, particularly when combined with Doppler studies, has proved to be diagnostic in the majority of patients with interatrial communications. These techniques allow accurate assessment of the size and location of the defect, as well as the degree of right ventricular volume overload. Both the M-mode and cross sectional echocardiogram are useful in detecting the most significant haemodynamic effect of an important atrial shunt, namely right ventricular enlargement. The classic M-mode echocardiographic findings are nearly always present when there is a large left-to-right shunt. Right ventricular dimensions are increased, and there is frequently flattened or paradoxical septal motion (Fig. 25-23).⁵⁸⁻⁶¹ Of the parameters used to judge the degree of left-to-right shunting, the ratios between pulmonary and aortic trunks and between the right and left ventricles were the most reliable indicators

Figure 25-23 The M-mode echocardiographic tracing from a patient with a defect in the oval fossa reveals the signs of an enlarged right ventricle and paradoxical septal motion.

of the size of the shunt.⁶² A ventricular ratio greater than 0.46, and an arterial ratio greater than equity, were almost always found in patients with a ratio of pulmonary to systemic flows of greater than 1.5. The lack of increase in right ventricular size with respiration has also been shown to be useful in differentiating a haemodynamically important shunt from one that is small.⁶³ Other causes of right ventricular volume overload may result in similar echocardiographic findings, including partially or totally anomalous pulmonary venous connection, and pulmonary and tricuspid regurgitation.

Although M-mode echocardiography can itself be diagnostic, nowadays cross sectional echocardiography has become the diagnostic technique of choice. It provides excellent visualisation of the atrial septum in multiple planes, with the most useful being the subcostal view.^{64,65} The apical four-chamber view may be unreliable in evaluation of the atrial septum, as artefactual echo dropout may simulate an atrial septal defect. The subcostal view allows imaging in a plane perpendicular to the atrial septum and can reliably define the site and approximate size of the defect. A defect of the oval fossa is seen in the central portion of the septum, while the sinus venosus and ostium primum defects are positioned superiorly and inferiorly relative to the oval fossa, respectively (Fig. 25-24). Pulmonary veins can usually be visualised and anomalous connections identified, for example in the sinus venosus defect.⁶⁶ The basic diagnostic feature of a superior sinus venosus defect, overriding of the superior caval vein and its biatrial connection, can be well demonstrated using echocardiography from the subcostal position (Fig. 25-25).^{14,67} An inferior sinus venosus defect is very uncommon, accounting for less than one-fifth of all the sinus venosus defects undergoing operative repair at Pittsburgh. Although difficult, this diagnosis can also be made by echocardiography.¹⁵ The features include a posterior and inferior location of the defect adjacent to the atrial connection of the inferior caval vein, and anomalous drainage of the right-sided pulmonary veins (Fig. 25-26). Although routine transthoracic studies are generally more than adequate for diagnosis in children, transoesophageal

echocardiography allows superb evaluation and visualisation of the atrial septum in patients with a poor standard echocardiographic window.^{68,69} Contrast echocardiography may provide supplementary information,^{24,70} but this is rarely necessary.

Doppler echocardiography, including pulsed wave studies and colour flow mapping, is an invaluable adjunct in the evaluation of interatrial communications (*Fig. 25-27*). Pulsed Doppler determination of the velocity of the trans-atrial shunt has been correlated with the ratio of flows of the pulmonary and systemic bloodstreams,⁷¹ but there

has been little enthusiasm for this technique in recent years. The degree of shunting can also be calculated using echocardiographic and Doppler measurements of flow across the right- and left-sided valves.⁷²⁻⁷⁴

Colour flow mapping is extremely useful in the evaluation of atrial shunts.²⁴ Flow across the defect can be clearly visualised, confirming that echo dropout is real rather than an artefact. The width of the flow gives some indication of the size of the defect, but we have found the reliability of colour flow in predicting size to be significantly limited by variability in gain settings and alignment of the scanning plane relative to the shunt. By combining direct echocardiographic imaging with Doppler studies, an interatrial communication can be well characterised.

An important aspect of interatrial communications has become apparent in recent years with the widespread use of echocardiographic and Doppler techniques. Small shunts in the region of the oval fossa can be demonstrated by Doppler interrogation in a high proportion of newborns and infants less than 3 months of age who have either no defect, or a very small one as judged by echocardiographic imaging.^{75,76} These shunts (*Fig. 25-28*) are presumably caused by incompetence of the flap of the oval foramen and will close within the first year of life. They should probably not be interpreted as true defects within the oval fossa.

Magnetic Resonance Imaging

Magnetic resonance imaging, as may be anticipated, is able to demonstrate interatrial communications.⁷⁷ The technique may also be useful for determining the degree of shunting, especially when other anatomical data not discerned on echocardiography is needed.⁷⁸ In view of the excellence of echocardiography for diagnostic purposes, we have not found it necessary to use this technique. Should a device have been used to close an atrial septal defect, there may be concern as to safety should the patient be subjected to powerful magnetic fields. In a phantom study of various devices, all but one of the currently available devices were found to be safe in fields having strengths up to

Figure 25-26 These cross sectional echocardiograms, in the subcostal view, demonstrate the features of an inferior sinus venous defect. *A*, The oval fossa is intact when a plane is taken through the mid-portion of the septum. *B*, Scanning inferiorly reveals the large interatrial communication between the right atrium (RA) and left atrium (LA). The defect is adjacent to the mouth of the inferior caval vein (*open arrow*). The right lower pulmonary vein drains into the right atrium (*solid arrow*).

Figure 25-27 Doppler echocardiograms of an atrial septal defect in the oval fossa from subcostal view. **A**, The mid-septal location of the defect (*white arrow*) can be seen. **B**, The colour flow map demonstrates left-to-right atrial shunting (*black arrow*) across a broad front. **C**, Pulsed Doppler shows the pattern of continuous flow of an atrial shunt with late systolic and early diastolic accentuation. The insert illustrates the position of the sample volume in the right atrium (RA) adjacent to the defect. LA, left atrium.

This is of no functional significance. LA, left atrium; RA, right atrium.

1.5 tesla, with no excessive heating noted, and minimal artifact induced in imaging.⁷⁹

Cardiac Catheterisation

Echocardiography and Doppler studies have now largely supplanted invasive studies in patients with atrial septal defects. Cardiac catheterisation continues to be the most precise method of quantifying the left-to-right shunt, and measuring intracardiac and pulmonary arterial pressures. It

is now also necessary to undertake catheterisation if interventional closure is to be attempted (see below). When the femoral venous approach is used, the catheter almost always passes easily through the mid-portion of the atrial septum into the left atrium when the defect is within the oval fossa. An attempt should be made to enter the pulmonary veins to confirm their normal connection to the left atrium.

An ostium primum defect may be recognised by a lower than usual atrial pass. It is usually easier to enter the left ventricle and more difficult to enter the pulmonary veins

when this type of interatrial communication is present. A sinus venosus defect is sometimes difficult to traverse when the approach is through the inferior caval vein. Considerable probing in the region of the superior cavoatrial junction may be needed to reach the left atrium. The lateral border of the proximal superior caval vein and right atrium should be explored for possible anomalous return of the right upper or middle lobe pulmonary veins, particularly if a sinus venosus defect is suspected.

The hallmark of an atrial shunt is a step-up in saturations of oxygen of at least 5% when moving from the superior caval vein to the right atrium. If the saturation in the superior caval vein is abnormally high, greater than 85%, anomalous pulmonary venous return must be considered. Saturations should then be obtained from the left brachiocephalic, right subclavian and right internal jugular veins. Anomalies other than an atrial septal defect that result in an increased saturation of oxygen in the right atrium include isolated partially anomalous pulmonary venous return, a ventricular septal defect associated with tricuspid insufficiency, a shunt from left ventricle to right atrium, and an aneurysm of the aortic sinus of Valsalva ruptured into the right atrium. Another potential pitfall in the use of oximetry for diagnosis stems from the fact that streaming of oxygenated blood directly across the tricuspid valve can occur such that a step-up in oxygenation is not evident proximal to the right ventricle. This is much more likely to occur with an ostium primum defect. Even when there is an isolated atrial septal defect producing a step-up in oxygenation in the right atrium, there may be a further step-up in the right ventricle. Samples from the left side of the circulation are fully saturated. The ratio of pulmonary-to-systemic flow can be calculated using oximetry and the Fick principle. This ratio is 2:1 or greater in over two-thirds of patients having clinically recognised defects.³³

Mean right atrial pressure is generally normal, but the magnitude of the V wave is usually equal to that of the A wave, with consequent loss of the normal dominance of the A wave. Phasic and mean pressures are commonly equal in the two atria if there is a large atrial septal defect, but there may be up to a 3 torr mean gradient across the defect. Right ventricular and pulmonary arterial pressures are almost always normal in childhood, but pulmonary hypertension may develop with increasing age.³¹ An occasional infant with a large atrial shunt has elevated pulmonary arterial pressure.³⁹ Pulmonary vascular resistance is usually normal or low, at 1 Wood unit or less, in children, but may be elevated in adults. Severe elevation of pulmonary vascular resistance with Eisenmenger's reaction is uncommon even in older patients, occurring in only about one-twentieth of individuals with an atrial septal defect.^{34,35} In some patients, the large flow of blood to the lungs causes a peak systolic gradient of 10 to 30 torr across a normal pulmonary valve, and/or a systolic gradient of 10 to 15 torr between the pulmonary trunk and its branches.^{18,19,30} Left atrial pressure is usually somewhat lower than normal, and left ventricular pressure is normal.

Indicator dilution studies may be useful in qualitatively and quantitatively evaluating a left-to-right shunt at the atrial level. The ratio of pulmonary to systemic flows calculated from such curves correlates well with that obtained by oximetry.⁸⁰ Selective pulmonary arterial injections of the indicator may suggest the presence of partially anomalous

pulmonary venous connection by showing variable magnitudes of shunting, and/or times of appearance from various portions of the lungs. It must be emphasised that functional return to the right atrium does not imply anatomical connection to the right atrium, since there may be remarkable streaming from normally connected veins. Cardiac output may be determined by injecting indicator into the left ventricle and sampling from the aorta.

Angiocardiography

A left ventriculogram may be useful in patients with an atrial septal defect, particularly if a high-quality echocardiogram is not available. This is helpful in determining the presence of an atrioventricular septal defect, mitral valvar prolapse, mitral insufficiency, left ventricular dysfunction or a ventricular septal defect. We usually prefer the antero-posterior and lateral views if a ventricular septal defect is not suspected, as this best demonstrates the gooseneck deformity of the left ventricular outflow tract and the trifoliate left atrioventricular valve of an atrioventricular septal defect. A right ventricular or pulmonary arterial injection in the anteroposterior and lateral views defines pulmonary arterial anatomy and pulmonary venous return and allows assessment of the magnitude of the atrial shunt during the laevophase. A right ventriculogram has the advantage of demonstrating right ventricular size as well as tricuspid valvar competency and pulmonary valvar anatomy. The pulmonary arteriogram has the advantage of avoiding arrhythmia at the time of the injection; it sometimes allows better definition of the pulmonary venous return. We have found that injection into the right upper pulmonary vein filmed in the four-chamber view⁸¹ is particularly helpful in confirming normal drainage of this vein, and may delineate the location and size of the atrial defect (Fig. 25-29). Any anomalously connecting pulmonary veins that are entered by the catheter should be selectively visualised.

DIAGNOSIS

The diagnosis of an interatrial communication can be made with virtual certainty when the classical findings of an ejection murmur at the high left sternal border, wide and fixed splitting of the second heart sound, and a medium-pitched mid-diastolic murmur at the low left sternal border are associated with typical radiographical and electrocardiographical findings. A sinus venosus defect with partially anomalous pulmonary venous return cannot usually be differentiated clinically from a defect within the oval fossa, but a low atrial rhythm, and/or an unusual shadow in the upper right hilum or the proximal superior caval vein on the chest radiograph, should lead one to suspect its presence. Left-axis deviation on the electrocardiogram, with or without a murmur at the apex suggesting insufficiency of the left atrioventricular valve, makes the diagnosis of an ostium primum defect very likely. Echocardiographic and Doppler studies are used to confirm the presence of an important left-to-right shunt with right ventricular volume overload and to characterise the size and location of the atrial defect. Several reports have shown that uncomplicated defects within the oval fossa, and sinus venosus defects, can safely be closed surgically with confirmatory non-invasive studies without routine preoperative

Figure 25-29 Pulmonary venous angiograms in patients with atrial septal defects. A, Right upper pulmonary venous angiogram in the four-chamber view reveals shunting across a defect in the oval fossa (between black arrows). B, Left upper pulmonary venous angiogram profiled in the left anterior oblique view reveals a sinus venosus defect (between white arrows), with shunting across the superior rim of the intact oval fossa. C, Right upper pulmonary venous angiogram in the four-chamber view shows shunting across an ostium primum defect (between black arrows). There is a common atrioventricular junction that is partitioned into separate left and right atrioventricular valvar orifices.

catheterisation.^{82,83} Although partially anomalous pulmonary venous connection may be undetected, or sinus venosus defects occasionally misclassified, this has not resulted in increased morbidity during operative repair. Currently, at our institution, cardiac catheterisation is performed only on patients in whom we insert a device to close the defect, and in those patients in whom the anatomy has not been completely defined by echocardiography.

Several common conditions must be considered in the differential diagnosis of a soft systolic ejection murmur at the upper left sternal border, including a functional murmur, mild valvar pulmonary stenosis and pulmonary arterial stenosis. Mild valvar pulmonary stenosis is virtually always accompanied by an early systolic ejection sound, and the murmur becomes strikingly louder with exercise. Pulmonary arterial stenosis has very prominent radiation of the systolic murmur to the back. These latter two anomalies have normal splitting of the second heart sound, lack a diastolic murmur at the low left sternal border and usually do not have evidence of right ventricular overload on the echocardiogram. A functional murmur is distinguished by an otherwise normal cardiovascular examination. Certain other abnormalities must be considered when a systolic ejection murmur at the upper left sternal border is associated with a medium-pitched diastolic murmur at the low-left sternal border. Ebstein's malformation usually has other auscultatory abnormalities, including a widely split first sound and/or a gallop. It can be definitively diagnosed by echocardiography. Congenital pulmonary stenosis and regurgitation may prove difficult to distinguish from an atrial septal defect on clinical grounds, but the diastolic murmur is best heard higher along the left sternal border and becomes louder in the recumbent position. Congenital tricuspid stenosis produces a diastolic murmur similar to that present with a large atrial defect. This anomaly is quite rare and should be apparent on the echocardiogram. A shunt from left ventricle to right atrium is another unusual entity that may be considered in the differential diagnosis, but the systolic murmur in this condition is loud and pansystolic and quite different from the systolic ejection murmur associated with an atrial defect. Partially anomalous pulmonary venous return without an associated atrial septal defect is a rare anomaly and usually requires cardiac catheterisation for diagnosis. Totally anomalous pulmonary venous return without obstruction may at times

present similar findings to a large atrial septal defect. The anomalous venous connections should be evident on the cross sectional echocardiogram, and the presence of a higher than expected haemoglobin for the age of the patient may suggest mild systemic desaturation. A common atrium may be associated with an atrioventricular septal defect and will be apparent on the echocardiogram. Occasionally, a functional mid-diastolic murmur at the left sternal border is not associated with any structural heart disease.⁸⁴ Another entity that may be confused is the straight back syndrome, with its systolic ejection murmur at the upper left sternal border and prominent pulmonary trunk on the chest radiograph. The lack of the normal thoracic kyphosis on the lateral chest radiograph is diagnostic.

COURSE AND PROGNOSIS

An isolated interatrial communication, even a large one, is usually well tolerated for many years.³² As has been noted, symptoms are usually minimal or absent during infancy and childhood. This is because the right ventricle is well adapted to pure volume overload,⁸⁵ and secondary pulmonary hypertension is usually a late complication. In the usual patient with an interatrial communication, the appearance of a large left-to-right shunt is delayed until the right ventricular hypertrophy present at birth regresses and right ventricular compliance increases. The pulmonary vascular bed, therefore, has time to mature, and can accept a large blood flow without an increase in pressure. In the absence of pulmonary hypertension, pulmonary vascular disease either fails to develop or follows an indolent course.

Symptoms tend to occur earlier and to be more severe when there is an associated anomaly, particularly one that tends to impede left atrial emptying through the mitral valve. Examples include obstruction of the left ventricular outflow tract, coarctation of the aorta, primary left ventricular myocardial disease, and mitral stenosis. In this respect, Lutembacher's syndrome refers to the combination of an atrial septal defect and mitral stenosis. It now seems to be quite uncommon, probably because of a decreasing incidence of rheumatic heart disease, and because of early closure of atrial septal defects. Non-obstructive associated anomalies may also lead to early congestive heart failure. Infants with both interatrial and interventricular communications, or a patent arterial duct, are likely to be

symptomatic because atrial shunting across even a small defect may be greatly augmented by the increased left atrial pressure caused by the associated lesion.

If impedance to left atrial emptying is markedly increased, and is present before the pulmonary vascular bed has had an opportunity to mature, the fetal pulmonary vascular pattern tends to persist, exaggerating the degree of pulmonary hypertension. Under these circumstances, signs of severe and rapidly progressive congestive heart failure may occur. An example is the infant who has both a severe aortic coarctation and an interatrial communication. The left ventricular dysfunction engendered by the coarctation raises left atrial pressure. This may produce a torrential left-to-right interatrial shunt along with severe congestive heart failure, which can be effectively treated only by correcting the coarctation.

Occasionally, infants with isolated and uncomplicated atrial septal defects may be symptomatic and experience congestive heart failure.^{38–40} It is not clear how these infants differ from asymptomatic ones, although it has been postulated that an atrial septal defect is usually small in infancy and grows large enough to produce symptoms only later in life. According to this formulation, the occasional infant with a large defect is the one who has symptoms early. It is much more likely, however, that a left-to-right shunt large enough to produce symptoms during infancy results from some unrecognised increased impedance to flow into the left ventricle, such as a subtle alteration in left ventricular compliance or an abnormality of the mitral valvar apparatus.⁷ Perhaps the situation is analogous to the older individual with an atrial septal defect that has been well tolerated for several decades. Such a patient develops a larger left-to-right shunt and becomes symptomatic following the appearance of left ventricular dysfunction, whether it is induced by systemic hypertension, coronary arterial disease or some primary myocardial abnormality.

Secondary pulmonary hypertension does eventually appear in some patients with an atrial septal defect. This is an important factor in the development of both the cyanosis and congestive heart failure that can complicate the course of the anomaly. The addition of a pressure load may compromise right ventricular function and lead to congestive heart failure, or to right-to-left shunting through the atrial defect even in the absence of overt failure. Cyanosis that appears only with congestive heart failure tends to disappear after treatment with diuretics or cardiotonic agents, while cyanosis occurring in the absence of failure tends to be permanent and is an important sign of irreversible pulmonary vascular disease. Pulmonary vascular obstructive disease, defined as a pulmonary vascular resistance greater than 7 index units, was found in one-twentieth of patients in one large series.³⁵ This finding was much more prevalent in females. Although a trivial degree of right-to-left shunting occurs in many individuals with an interatrial communication,²¹ sufficient shunting to produce recognisable cyanosis is distinctly unusual in an uncomplicated atrial defect. If the atrial septum is rudimentary, or entirely absent, some right-to-left shunting is usual and there may be mild cyanosis. Anomalies of systemic venous return are not common but may be responsible for cyanosis in an occasional patient with atrial septal defect. Drainage of a persistent left superior caval vein to the left atrium can be part of a developmental complex associated with an

interatrial communication at the orifice of the coronary sinus.⁸⁶ Inferior caval venous drainage may be anatomically or functionally anomalous, with flow to the left atrium or to both atriums. This most commonly occurs with an inferior type of sinus venosus defect since the inferior caval vein overrides the interatrial septum. It has also been reported with defects in the oval fossa associated with overriding of the inferior caval vein.¹⁴

Although spontaneous closure of an atrial septal defect is less common than spontaneous closure of a defect in the interventricular septum, numerous authors have reported such closure, with an incidence varying from 3% to 67%.^{38,75,87–89} This marked variability in estimated rates of closure results from several factors. The incidence is higher when the atrial defect is detected in the first year of life, as illustrated by the closure rate of more than half in one series.⁸⁷ Another important factor is that ascertainment of atrial shunts has been dramatically increased in recent years by the remarkable sensitivity of Doppler and cross sectional echocardiography.⁷⁵ Undoubtedly, many of these atrial shunts detected in early infancy result from transient incompetence of the flap of the oval fossa and are not defects within the fossa. The former should be considered a normal variant, and can be identified when the atrial septum is virtually intact echocardiographically but there is a small atrial shunt on colour flow mapping (see Fig. 25-28).

In a review at the Children's Hospital of Pittsburgh, the overall rate of spontaneous closure was only 3%.⁹⁰ The natural history may have been affected in some patients by surgical intervention before the age of 4 years. Surprisingly, factors such as age at presentation, symptoms, magnitude of shunt, size of the defect, or degree of right ventricular volume overload did not predict which patients would undergo spontaneous closure or decrease in size of their defects. The mechanism of closure is uncertain, but has been ascribed to an atrial septal tissue flap⁸⁹ or, in some cases, to aneurysm of the oval fossa.^{90,91}

Atrial arrhythmias are relatively uncommon in children with atrial septal defects, but they tend to become more common with advancing age.^{32,37,41,42,92,93} Atrial flutter or fibrillation occurs frequently in older individuals, with a large left-to-right shunt and an enlarged right atrium being found in two-thirds of patients in one series.⁴¹

Rarely, paradoxical embolism may occur, with a clot from a pelvic or leg vein crossing the defect and entering the systemic circulation. As has been discussed above, a small right-to-left shunt is not uncommon in patients with an atrial septal defect. This may be augmented during a Valsalva manoeuvre or similar activities such as straining at stool. Other studies have shown that patency of the oval foramen, even without an atrial shunt, may be a risk factor for strokes in young adults.^{94,95} Infectious endocarditis is a very rare complication of an atrial septal defect unless there is a predisposing associated anomaly.⁸

Studies of natural history in patients with atrial septal defects who have not undergone surgical correction suggest an average life expectancy between 36 and 49 years, with three-quarters of patients dying before age 50 years, and nine-tenths by 60 years.^{32,41,96,97} Longevity, however, was much greater in the absence of pulmonary hypertension.⁹⁸ Although symptoms are very uncommon in the first several decades of life, dyspnoea and fatigue with

exertion become more prevalent in adulthood and are experienced by the majority of patients over 50 years of age.⁹⁹ Approximately two-thirds of patients older than 40 years of age will have one or more of the complications discussed above, such as congestive heart failure, pulmonary hypertension, atrial arrhythmias or paradoxical embolisation.³ Because the data from these studies were largely gathered in an era when associated rheumatic mitral valvar disease was more common, they probably do not accurately reflect the current life expectancy of an individual with an isolated atrial septal defect. A more benign natural history can now be predicted for asymptomatic or minimally symptomatic patients who present after 25 years of age,¹⁰⁰ with findings in this study equivalent to the results from a similar group of patients who underwent surgical repair.

MANAGEMENT

As has been noted, symptoms rarely occur in children with interatrial communications. An attempt at medical management with digitalis and diuretics is worthwhile in the occasional infant who presents with congestive heart failure, since several studies have shown that many of these children will have spontaneous closure of the defect or, at least, will have abatement of their symptoms.^{38,39,40,87,101} Closure is clearly indicated in all children with ratios of left-to-right shunting of greater than 2 to 1 to prevent eventual pulmonary hypertension, congestive heart failure, and atrial arrhythmias. When the defect is small, and the ratio of flow is estimated to be less than 1.5 to 1, closure is probably not indicated, since late sequels are rare, and life expectancy is probably normal. The ease of closure using a device, nonetheless, combined with the increasingly recognised association between cryptogenic stroke and small atrial communications, has resulted in many interventionalists adopting a more aggressive approach in recommending closure of small defects. With borderline shunts having ratios of flow between 1.5 to 1 and 2 to 1, various features, including presence of a murmur of tricuspid flow, right ventricular enlargement, the size of the defect on the echocardiogram, and radiographic findings, should be considered when evaluating the need for closure. Our current approach is to recommend closure if there is definite evidence of right ventricular enlargement, or if there are signs of respiratory compromise, particularly in infants with a history of chronic respiratory disease. There are no data to suggest that there is any risk to the patient in delaying closure for several years in the hope that the magnitude of the shunt may decrease. The only contraindication to closure is pulmonary vascular disease, evidenced by marked elevation of pulmonary vascular resistance. When closure was achieved only by surgery, high operative mortality and decreased life expectancy were reported for patients who underwent repair in the face of pulmonary vascular disease.⁹⁸ On a more optimistic note for this group of patients, a review more reflective of the modern surgical era demonstrated a low perioperative mortality rate and improved prognosis in surgically versus medically treated patients with total pulmonary vascular resistance between 7 and 15 index units.³⁵

The timing of elective closure does not seem to be crucial. As spontaneous closure becomes increasingly uncommon after 2 years of age, we recommend correction any time

after this age. There is probably a psychological advantage in accomplishing repair prior to the school years. In addition, if open surgical repair is required, performing this at an older age may be done successfully without exposing the child to blood products. Earlier intervention is indicated if there is marked cardiomegaly, failure of growth, or congestive heart failure. Although significant impairment of growth is only rarely seen in childhood, a post-reparative growth spurt can be expected.¹⁰²

Until relatively recently, there was no choice in terms of the technique for closure. Open heart repair of interatrial communications has been carried out with excellent success for many years, and the operative mortality is now expected to be zero in centres experienced in surgical correction of congenital cardiac malformations. The surgical approach to defects within the oval fossa consists of either direct suture or patch closure, depending on the size of the opening. When a sinus venosus defect is present, a patch is always necessary. It can usually be placed so as to close the interatrial communication and, at the same time, redirect anomalously draining pulmonary veins into the left atrium. Perioperative complications are rare. They include the postpericardiotomy syndrome and transient arrhythmias. Air embolisation is an uncommon but tragic complication. It is more likely when a right lateral thoracotomy is used, since this approach makes evacuation of air more difficult. Obstruction at the superior caval vein may rarely occur following repair of a superior sinus venosus defect, while a misplaced patch during the repair of an inferior defect may result in cyanosis due to shunting from the inferior caval vein to the left atrium.

The long-term results of surgery are excellent, and residual shunts are very rare. Resolution of cardiomegaly as seen on the chest radiograph, and of right ventricular hypertrophy seen on the electrocardiogram, are expected. Radiographic evidence of cardiac enlargement can persist in some patients,⁵⁶ as can right ventricular enlargement as revealed by echocardiography.¹⁰³ Actuarial survival calculated over 27 years for patients undergoing surgery at less than 24 years of age was identical to controls.⁴¹ In contrast, a review of more than 100 patients who underwent surgery at less than 14 years of age, and were followed for an average of 14.5 years, revealed right ventricular dilation in one-quarter.¹⁰⁴ Numerous studies have also shown surgical intervention in adults, even those older than 60 years, to be safe and effective.^{41,100,105–107}

Arrhythmias, including sinus nodal dysfunction, supraventricular tachycardia, and atrioventricular disturbances of conduction, do occasionally occur after repair of atrial septal defects.^{43,56,108} Implantation of pacemakers may be required in a small number of patients.^{104,108} The incidence of tachyarrhythmias, particularly atrial flutter or fibrillation, increases with age at operation.^{93,109} Patients with sinus venosus defects appear to be more at risk for bradyarrhythmias than those with defects within the oval fossa.¹¹⁰ We found that one-third of patients at the Children's Hospital of Pittsburgh with sinus venosus defects had persistent sinus nodal dysfunction after surgery. In contrast, less than one-sixth with defects in the oval fossa had post-operative sinus nodal dysfunction, and a pacemaker was required in only one patient. Although it has been presumed that these post-operative arrhythmias result from intra-operative damage to nodal or conduction tissue, numerous intracardiac

Figure 25-30 An ASDOS device, demonstrating the principle of devices that close interatrial communications by placing umbrellas to either side of the rims of the oval fossa. **A**, The umbrellas separated. **B**, The umbrellas in profile once they are connected. (Reproduced by permission of the late Professor Gerd Hausdorf and the publishers of *Cardiology in the Young*.)

electrophysiological studies show a high pre-operative incidence of sinus nodal and, to a lesser extent, atrioventricular nodal, dysfunction in patients with atrial septal defects in the oval fossa.^{43,44,45,46} Because bacterial endocarditis is so rare with isolated secondary atrial septal defects, antibiotic prophylaxis is no longer recommended.^{8,111}

As an alternative to surgical correction, patients with atrial septal defects within the oval fossa are now increasingly submitted to closure by means of interventional catheterisation. The technique was initially used some time ago,^{112,113} but the devices employed were cumbersome. More recently, the double umbrella device known as the Clamshell occluder, developed by Lock and his colleagues,¹¹⁴ was used successfully to close atrial defects in more than 200 patients.^{115–118} Effective closure was achieved in more than nine-tenths, but clinical trials with this initial device had to be suspended because of a high incidence of fracture of its arms. At least five new devices have now been the subject of clinical trials.¹¹⁹ These are CardioSEAL, the modification of the initial Clamshell device; various generations of the Sideris buttoned device^{120–122}; the ASDOS occluder^{123,124}; the self-centring AngelWings device^{125,126}; and the nitinol Amplatzer septal occluder.¹²⁷ The first four of these devices are designed to close the defect by means of a membrane placed on one or both sides of the rims of the oval fossa (Fig. 25-30). All of these devices have arms that stabilise the membrane against the atrial wall. The Amplatzer device, in contrast, is a dumbbell-shaped nitinol plug that stents the defect, sitting like a peg within it (Fig. 25-31). As Bjornstad comments, it is unlikely that all five of these devices will survive.¹¹⁹ It is also possible that the optimal device has not yet been made, though the Amplatzer septal occluder has gained wide popularity, primarily because of its ease of deployment and recapture.

Figure 25-31 The stages of deployment of the nitinol Amplatzer plug. Stage D is the first point at which centring is possible. (Reproduced by permission of Drs J. L. Wilkinson and T. H. Goh, and the publishers of *Cardiology in the Young*.)

This procedure has evolved somewhat over time. Bjornstad has highlighted some of the caveats concerning the insertion of these devices, and the choices of interventional closure as opposed to surgery.¹¹⁹ Not all defects within the oval fossa are suitable for closure,^{128,129} so careful selection of patients is mandatory.^{130,131} As discussed above, surgical closure has a low rate of complications, leaves very little residual shunting, and can now be achieved with virtually no mortality. Note has also to be taken of the more recent trend to undertake less-invasive surgical procedures, which limit the surgical incision without compromising exposure.^{132–134} Interventions to close atrial septal defects produce results comparable to those obtained with these most recent surgical innovations.¹³⁵ The procedure of closure using the Amplatzer device is relatively simple and effective (Fig. 25-32), with complete closure achieved in over nine-tenths of one series as based on initial echocardiographic follow-up.¹²⁷ Closure with a device can be complicated by endocarditis. Since these initial reports, interventional closure of defects within the oval fossa has become the treatment of choice. Closure of atrial septal defects within the oval fossa, therefore, will increasingly become the province of interventionists, just as they have monopolised the therapy for valvar pulmonary stenosis and patency of the arterial duct.¹¹⁹

While the technical aspects of closure of defects within the oval fossa using a device inserted through a catheter are beyond the scope of this chapter, several key issues must be noted. Anticoagulation during the procedure and afterward is particularly critical to avoid formation of thrombus on the device, which could lead to pulmonary or systemic vascular embolism. A combination of aspirin and clopidogrel has been demonstrated to be effective in preventing such formation.¹³⁶ A second issue arises with defects which are difficult to close. On occasion, the Amplatzer device will assume a position perpendicular to the plane of the atrial septum, with the left atrial disc prolapsed into the right atrium. This can occur with large defects, with defects possessing small rims of tissue for anchoring of the device, or

in younger patients with relatively smaller hearts. Various techniques have evolved to assist in closure of such defects, including use of a balloon to support the left atrial disc during deployment,¹³⁷ use of the right or left upper pulmonary vein for positioning of the delivery sheath,¹³⁸ use of a modified straight delivery sheath to facilitate angled delivery of the left atrial disc,¹³⁹ and use of a Hausdorf sheath or a Judkins right coronary guiding catheter.¹⁴⁰ We have found that closure of large defects, while technically more challenging, is readily accomplished, and should always be considered unless there is an absence of rims surrounding the defect, particularly along the floor or anteriorly. Additionally, our experience with closure of defects in children under 1 year of age, always undertaken due to co-existent respiratory compromise, has been favourable. In addition to the absolute size of the defect, the rims of the defect play an important role in determining the suitability for closure. Typically, the adequacy of the rims is easily assessed by transthoracic echocardiography prior to undertaking catheterisation, though a deficiency of the inferior rim may escape detection until a transoesophageal study can be performed.

An important complication, which can occur both early and late after closure, is erosion of the device along its edges into adjacent structures. Typically, such erosions occur into the aortic root, though damage to the primary septum has also been reported.¹⁴¹ Erosions into the aortic root are considered due in part to oversizing of the device, and may also be more common in patients with deficiency of the superior or aortic root rims of the defect. Recommendations on how best to avoid this potentially lethal complication include avoidance of overstretching the defect during balloon-sizing, which can lead to selecting a larger device than is necessary. In general, the device implanted should not be greater than 50% larger than the unstretched diameter of the defect. Additionally, patients with deficient superior or aortic rims should be followed closely, especially if any pericardial effusion develops within 24 hours of device implantation.¹⁴²

Division of Atrial Chambers

ROBERT H. ANDERSON and ANDREW N. REDINGTON

Division, or partitioning, of one of the atrial chambers is a rare malformation. Severe symptoms, or even death, may ensue if it is untreated. When recognised, and treated surgically, life expectancy should be normal. Either the morphologically right, or the morphologically left, atrium can be divided by fibromuscular partitions. Division of the morphologically left atrium is by far the most common, and the most important, type. When used in isolation, the term *cor triatriatum* almost always refers to the divided left atrium.¹ For those who prefer classical terminology, it is more accurate to describe either *cor triatriatum sinister* or *cor triatriatum dexter*. For those who prefer the vernacular, the lesions can be described simply as divided left or right atriums. Division of one or other atrium was the rarest lesion, bar one, in the files of the Hospital for Sick Children, Toronto, when they were used for the classical textbook emanating from that institution.² Despite their rarity, the malformations are sufficiently well circumscribed anatomically to warrant their own chapter in our book.

DIVIDED MORPHOLOGICALLY LEFT ATRIUM

Morphology and Morphogenesis

Church³ is usually credited as being the first to describe division of the left atrium, albeit that it was Borst⁴ who coined the term *cor triatriatum*. Since then, there have been several classifications, not all of which are restricted to cases that represent a congenitally partitioned left atrium. James,⁵ for example, included examples of totally anomalous pulmonary venous connection to the coronary sinus in his grouping, together with aneurysms of the atrial septum, neither of which would now be considered as examples of divided left atrium. Thilenius and his colleagues⁶ proposed a much expanded concept, which included rare cases reported in the literature with atresia of the mouth of the coronary sinus and anomalous pulmonary venous connection to a midline additional chamber, which then drained to the morphologically right atrium. They also described a further solitary case, with mitral atresia, in which there was a midline atrial compartment that received neither systemic nor pulmonary veins. As they indicated, it is as well to be aware of these variants. There is little doubt, however, that almost all cases encountered in clinical practice will be of the classical type. It is this anomaly, typically called *cor triatriatum sinister*, with which we shall be concerned in the remainder of this chapter.

In the typical lesion, an obliquely orientated fibromuscular partition divides the morphologically left atrium into a proximal compartment which is connected to the

pulmonary veins, and a distal portion in communication with the atrial appendage and the mitral valvar vestibule (Fig. 26-1). These components of the left atrium have been described in various ways, such as superior and inferior, upper and lower, common pulmonary venous and left atrial, and accessory and left atrial chambers. In this respect, the terms proximal and distal have themselves been used with opposite meanings, according to the fashion in which they are perceived. We agree with Thilenius and his colleagues⁶ that it is sensible to name the chambers according to the direction of flow of blood.

Although all the examples falling within the characteristic pattern have the oblique dividing partition, there is still scope for considerable anatomical variability. The significant variations are the size of the communication between the proximal and distal compartments, the site of an inter-atrial communication, if present, and the connection of the pulmonary veins, although any other associated malformation can co-exist. The communication between the compartments can vary from being non-restrictive, which is rare, to the more usual arrangement in which there is a pinhole meatus (Fig. 26-2). Usually the communication is single, but multiple orifices can be found. The atrial septum is intact in up to half of patients. When present, a septal defect is almost always within the oval fossa. It most

Figure 26-1 This heart with division of the left atrium is photographed from the left side. The partition divides the chamber into a distal component, which receives the pulmonary veins, and into which the oval foramen opens, and a proximal part, made up of the vestibule of the mitral valve and the left atrial appendage.

Figure 26-2 The heart shown in Figure 26-1 has been reconstituted and sectioned to replicate the echocardiographic four-chamber view. Note the oblique dividing shield, with only a pinhole meatus between the two subcomponents of the left atrium. Note also that the oval fossa opens to the distal component.

frequently communicates with the distal compartment (see Figs. 26-1 through 26-3). In the series reported by Thilenius and his colleagues,⁶ nonetheless, about one-quarter of their classical cases were found with the oval fossa in communication with the proximal atrial component. Almost always the atrial communication is within the oval fossa, albeit that rare cases have been described where the communication with the distal chamber is an atrioventricular rather than an atrial septal defect.⁶ One case of divided left atrium has also been found in the setting of an atrioventricular septal defect with intact septal structures.⁷ Just as the morphology of the interatrial communications can vary, so can their size. While the pulmonary veins usually connect to the distal atrial compartment, many types of partially anomalous venous connection are described, and it such associations that, for the most part, account for the exceedingly complex categorisation designed by Thilenius and his colleagues.⁶ We prefer to account for these uncommon associated lesions in descriptive fashion. As emphasised, any other lesion can co-exist with a divided left atrium, including such malformations as mitral atresia,⁸ and discordant atrioventricular connections.⁸ The dividing partition itself is made up of a double layer of myocardium, arguably giving clues as to the morphogenesis of the lesion.^{9,10} The right side of the heart is usually considerably hypertrophied when the left atrium is partitioned. In keeping with this, as with other cases of obstructed pulmonary venous return, there are marked changes within the lungs,¹¹ with varicose dilation of the alveolar capillaries, concentric medial thickening of the pulmonary arterioles with luminal narrowing. There can also be prominent dilation of the pleural lymphatics.¹² Division of the left atrium was conventionally explained on the basis of failure of absorption of the common pulmonary vein into the left atrium. This malincorporation hypothesis was then replaced by the entrapment concept.¹⁰

This concept was based on the belief that the primary pulmonary vein, during its development, was caught in a vice between the left sinus horn and the rest of the systemic venous sinus. The concept accounts well for the classical anomaly. It less readily explains the variant in which the atrial septal defect, unequivocally at the oval fossa, communicates with the proximal chamber. It is possible, however, to combine concepts of malseptation with the entrapment hypothesis to account for these variants. As Thilenius and his colleagues rightly commented,⁶ all these theories are of necessity speculative.

Incidence and Aetiology

As already discussed, division of the left atrium represented less than 0.1% of the case load in the files of the Hospital for Sick Children, Toronto.² Only four examples were found in nearly 4000 catheterisations performed at the Royal Brompton Hospital from 1970 through 1982.¹³ Males are affected more frequently than females.^{6,14} There has been no observed aetiology for the lesion, although it is suggested¹⁵ that the partition may be induced during development by persistence of the left superior caval vein. Although superficially attractive, it is difficult to reconcile this hypothesis with the fact that so few patients with persistent left caval veins also have a divided left atrium.

Presentation and Clinical Features

The age and mode of presentation relate to the tightness of the communication between the proximal and distal chambers. Presentation with symptoms usually implies a small communication, but symptoms will be amplified in the presence of a left to right shunt. Usually, patients then present in infancy, or early childhood, with dyspnoea and frequent respiratory infections, although presentation with congestive heart failure, unexplained pulmonary hypertension, and haemoptysis in adult life is well-described. The cases presenting earlier do so with tachypnoea with or without cyanosis, as in totally anomalous pulmonary venous connection. When cyanosis is present, this usually is the consequence of a right-to-left shunt from the right atrium through an oval foramen or atrial septal defect to the distal compartment of the divided left atrium. Partially anomalous pulmonary venous connection, when present, removes the chance of cyanosis, and may alleviate the obstructive symptoms.¹⁶

The clinical signs are dominated by evidence of pulmonary venous congestion and pulmonary hypertension. The child will be pale and sweating, with tachycardia, and extreme breathlessness on feeding, but usually will remain fully saturated. There is a right ventricular heave and, on auscultation, the pulmonary component of the second sound is almost always accentuated. No murmurs may be heard, although an apical diastolic murmur may simulate mitral stenosis. A soft, blowing systolic murmur may represent secondary tricuspid regurgitation in severe disease. Occasionally the apical murmur is continuous, or the early diastolic murmur of pulmonary incompetence may be heard secondary to pulmonary hypertension. The signs of congestive heart failure are found when this supervenes, including crepitations in the lungs and a palpable liver.

Investigations

The chest radiograph usually reveals cardiomegaly and shows the presence of pulmonary venous obstruction. The so-called staghorn, or butterfly wing, sign is seen because of prominent venous engorgement of the upper pulmonary veins. Pulmonary arterial hypertension is reflected by a prominent pulmonary knob.

Right ventricular hypertrophy is almost invariably present on the electrocardiogram. The frontal mean QRS axis is usually between $+120$ and $+140$ degrees. Apart from broad P waves, which are sometimes present as a consequence of right atrial hypertrophy, the rhythm and remainder of the electrocardiographic pattern are usually within normal limits.

Cross sectional echocardiography (Fig. 26-3) is the definitive investigation, permitting direct visualisation of the obstructive partition, and showing the site of interatrial defects, if present. The technique should also permit the recognition of any associated malformations. Doppler studies will then help clarify the situation. The position and size of the communication between the distal and proximal chambers are often best delineated by colour flow mapping (Fig. 26-4), while spectral Doppler studies will define the pressure difference between the two (Fig. 26-5).

It will be rare nowadays that invasive investigation is necessary for diagnosis. If performed, however, the haemodynamic findings can be highly suggestive of the usual form of divided left atrium. An elevated pulmonary arterial wedge pressure is found in the presence of normal pressure tracings in the distal left atrial chamber and left ventricle.

Differential Diagnosis

In infants and children, this lesion has to be distinguished from other causes of pulmonary venous obstruction. It may be difficult to differentiate totally anomalous pulmonary

Figure 26-4 Colour flow mapping in the patient shown in Figure 26-3 reveals turbulent flow across the communication between the distal and proximal chambers.

venous connection from pulmonary venous obstruction, since the conditions may have similar clinical, radiological, and electrocardiographic findings. Most patients with divided left atrium will be fully saturated while breathing 100% oxygen, in contrast to most patients with totally anomalous pulmonary venous connection. The two are readily distinguished by echocardiography, even when the partitioned left atrium is itself associated with anomalous pulmonary venous connections. The other conditions to be distinguished in infancy and childhood are congenital

Figure 26-3 The cross sectional echocardiogram shows the features of divided left atrium.

Figure 26-5 Spectral Doppler recording in the patient shown in Figures 26-3 and 26-4 reveals the velocity of flow at the communication between distal and proximal chambers of the left atrium. There is continuous flow at high velocity, suggesting severe stenosis and pulmonary venous hypertension secondary to peak and mean gradients of 44 and 19 mm Hg, respectively.

stenosis of individual pulmonary veins, atresia of the common pulmonary vein, supra-valvar stenosing ring of the left atrium producing the so-called hourglass left atrium, congenital mitral stenosis, and perhaps endocardial fibro-elastosis with severe aortic stenosis. In older patients, there is a quite different differential diagnosis. Rheumatic mitral stenosis, or left atrial tumour or thrombus, are then the most likely alternatives. A more important differential diagnosis is obstruction of the vestibule of the left atrium by persistence of the left superior caval vein draining to the coronary sinus. Several examples of the latter lesion have now been documented in which symptoms were relieved subsequent to surgical plication of the caval vein.¹⁷ It should be an easy matter to distinguish the entity from divided left atrium using cross sectional echocardiography.

Treatment

The only appropriate treatment is surgical. The dividing partition is resected on cardiopulmonary bypass. This is usually achieved via a right atrial incision, visualising the partition through the oval foramen or an atrial septal defect. The shelf can also be removed via a left atrial incision. Medical treatment is indicated initially for those patients in heart failure, but only until the diagnosis is made. Surgery nowadays should carry zero mortality, and carries an excellent prognosis.

DIVIDED MORPHOLOGICALLY RIGHT ATRIUM

Division of the morphologically right atrium is considerably rarer than that of the left. It results from persistence of the valves of the embryonic systemic venous sinus.¹⁸ The dividing partition, therefore, is placed between the systemic venous sinus and the distal part of the right atrium, made up of the vestibule and appendage. The embryonic valvar structures, whose significance during fetal life is to direct the richly oxygenated inferior caval venous blood across to the left atrium and thence to the aorta, normally regress in late fetal life and early childhood. They persist as the Eustachian and Thebesian valves, the valves of the inferior caval vein and coronary sinus, respectively. These valves can retain their fetal proportions in abnormal conditions and then divide the right atrium. The dividing partition can itself be fenestrated so as not to produce major obstruction to the flow of blood. This is termed a Chiari network, and may not produce problems (Fig. 26-6). If, in contrast, the persisting valvar structures are not fenestrated, then they can produce partitions within the right atrium. Most examples seen in postnatal life have co-existed with atresia or stenosis of the pulmonary valve, or else with tricuspid atresia (Fig. 26-7).¹⁸

The haemodynamic effect of the partition itself is then of little significance, since the blood is required to cross the oval fossa, and the persistent valve augments this pattern of flow, albeit that the opening of the superior caval vein may not be included within the partitioned venous sinus (see Fig. 26-7). The lesion is of more significance when the tricuspid and pulmonary valves are patent, when the persisting valve can become aneurysmal and protrude into the right ventricle like a windsock (Fig. 26-8).

Figure 26-6 In this heart, the valves of the embryonic venous sinus have persisted in postnatal life, but have become fenestrated, producing the so-called Chiari network.

Figure 26-7 This heart also exhibits postnatal persistence of the valves of the embryonic venous sinus, but unlike the heart shown in Figure 26-6, the valves have not become fenestrated, so that they produce a partition between the systemic venous sinus and the appendage of the morphologically right atrium. In this heart, however, there is co-existing tricuspid atresia due to absence of the right atrioventricular connection, so that the partition merely exaggerates the flow of blood from the inferior caval vein to the patent oval fossa, as shown by the large piece of red tape cut in the shape of an arrow.

Figure 26-8 In the patient from whom this windsock was removed, the valves of the embryonic venous sinus had become aneurysmal, and herniated through the tricuspid valve, obstructing the flow of blood through the right side of the heart.

Figure 26-9 The cross sectional echocardiogram shows division of the morphologically right atrium produced by persistence of the valves of the embryonic systemic venous sinus.

Surgical removal is an easy matter once diagnosis has been made.¹⁸ Diagnosis is now readily made using cross sectional echocardiography¹⁹ (Fig. 26-9), albeit that the aneurysmal valve does not always produce symptoms, and can be a chance finding.²⁰

Atrioventricular Septal Defects

TJARK EBELS, NYNKE ELZENGA, and ROBERT H. ANDERSON

There is a group of lesions unified by the anatomical hallmark of a common atrioventricular junction co-existing with deficient atrioventricular septation. The key to their differentiation from other potentially related defects is the presence of the common junction, including the arrangement of the fibrous skeleton of the heart, which is fundamentally different from the morphology found either in the normal heart, or in patients with separate right and left atrioventricular junctions. In clinical terms, it is probably the influence of this abnormal architecture of the atrioventricular valves that is the most prominent feature. In this respect, there is a common atrioventricular junction irrespective of whether there are separate atrioventricular valvar orifices for the right and left ventricles, the lesion traditionally described as the ostium primum defect, or whether the valve itself is also a common structure, often described as the complete form of the malformation. As we will show, the abnormal morphology of the ventricular mass and the atrioventricular junction is more or less constant within the overall group, thus calling into question the notion of distinguishing between partial and complete variants. Also described previously as endocardial cushion defects, or atrioventricular canal malformations, we describe the lesions here simply as atrioventricular septal defects,¹ this term slowly coming to achieve recognition as being the most accurate descriptor. Very rarely, nonetheless, hearts with deficient atrioventricular septation can exist with otherwise normal atrioventricular junctions.² Patients with all the stigmas to be described in this chapter can also be found, again rarely, when the septal structures are intact,^{3,4} presumably due to spontaneous closure of a preexisting atrioventricular septal defect.⁵ Notwithstanding these potential caveats, it remains our conviction that atrioventricular septal defect is the best default option for this important group of malformations. For precision, nonetheless, it is necessary also to specify the presence of the common atrioventricular junction, and to indicate spontaneous closure in those rare instances when the septal structures are intact despite the presence of the common junction.⁵

PREVALENCE AND AETIOLOGY

Early reports of the prevalence of atrioventricular septal defects with common atrioventricular junction varied markedly.^{6,7} These differences almost certainly reflect the problems inherent in most epidemiological studies due to the bias in selection. The most accurate data is that provided by study of a stable population backed up with verification at clinical study or autopsy. Using such an approach,

Samanek et al⁸ calculated a prevalence of 0.19 per 1000 live births, which accounted for 2.9% of the patients examined with congenitally malformed hearts. Of the cases identified in Bohemia, three-fifths had shunting confined at atrial level, the so-called ostium primum defects, while the remainder had associated ventricular shunting. A marked seasonal variation was found, with the highest incidence in March, July, and October, and the lowest in May. These differences were unlikely to be due to chance. Regional differences were also found, with most of the afflicted children being born in industrial areas, and girls just predominated in the overall numbers. The lesion was even more frequent in stillborns, accounting for 6.2% of all congenitally malformed hearts.⁸

There is a strong association of deficient atrioventricular septation with Down's syndrome (see Chapter 9). In Toronto, about one-third of patients with Down's syndrome had an atrioventricular septal defect with common valvar orifice, while only one-twentieth had the so-called ostium primum variant.⁹ In the Bohemian population, half of those with deficient atrioventricular septation had Down's syndrome.⁸ This close association with trisomy 21 is cited as evidence against the usual multi-factorial model put forward to explain the inheritance of congenital cardiac disease.¹⁰ Evidence has been found of autosomal dominant inheritance, not linked to chromosome 21, in large families involving many patients with atrioventricular septal defect,¹¹ and there is appreciable evidence of familial recurrence.^{12,13} It is possible, therefore, to discern at least three different genetic patterns, one found in association with Down's syndrome, a second emerging as an autosomal dominant trait, and the third being isolated. There is a high rate of recurrence, particularly in females. Major anatomical differences are present within the overall population of patients having atrioventricular septal defects with or without Down's syndrome, such as the atrioventricular valve being common or divided into separate left and right valvar orifices. It is intuitive to suggest that these differences must be a reflection of the different genetic mechanisms involved.¹⁴

ANATOMY

Basic Morphology of the Atrioventricular Junctions

It is the structure of the atrioventricular junctions which provides the phenotype for the group of lesions under discussion.¹⁵ By atrioventricular junctions, we mean those areas of the heart where the atrial myocardium becomes contiguous with the ventricular myocardium. In the normal heart, the myocardial segments within these areas are completely

Figure 27-1 This normal heart has been sectioned in four-chamber fashion to show the separateness of the normal atrioventricular junctions, one for the tricuspid valvar orifice and the other for the mitral valve (*white double-headed arrows*). Note that, apart from at the site of the penetrating bundle (*green arrow*), the atrial myocardium is separated from the ventricular myocardium by the fibro-fatty tissues of the junctions. Note also the off-setting of the attachments of the mitral and tricuspid valves at the septum (*red arrows*). AV, atrioventricular.

separated from one another, save for the site of penetration of the muscular axis responsible for atrioventricular conduction, this being the bundle of His (Fig. 27-1). The separation within the junctions, providing the necessary electrical insulation, is produced largely by the fibro-fatty tissues of the atrioventricular grooves, which account for the greater part of the so-called valvar annuluses. These annuluses also support the attachments of the leaflets of the atrioventricular valves. In the normal heart, of course, there are two atrioventricular valves. It follows, therefore, that there are also two atrioventricular junctions, which surround the tricuspid and mitral valvar orifices.¹⁶ There is then a complex junctional component present between these orifices, which also abuts the subaortic outflow tract. The morphology of the normal junctions is such that this septal component is relatively small. This is, in part, because the left ventricular outflow tract, incorporating the orifice of the aortic valve, is deeply wedged between the diverging antero-superior margins of the mitral and tricuspid valve (Fig. 27-2). Furthermore, over a significant part of the left atrioventricular orifice, there is not even the potential for contiguity between the atrial and ventricular myocardial masses. This is because of the extensive area of fibrous continuity that exists between the leaflets of the aortic and mitral valves. The right and left margins of this region of valvar fibrous continuity are thickened to form the right and the left fibrous trigones, respectively (see Fig. 27-2). The right trigone is itself combined with the membranous septum to form the central fibrous body. It is the arrangement of the junctional component between the valvar orifices that is most pertinent to the morphology of atrioventricular septal defects. In the apparently septal component, small as this may be, the septal leaflet of the tricuspid valve is attached at a considerably more apical level than is the corresponding leaflet of the mitral valve (see Fig. 27-1). In this area, the atrial myocardium overlaps the crest of the muscular ventricular mass, with an extension of the insulating infero-posterior fibro-fatty atrioventricular groove separating the

Figure 27-2 This normal heart is sectioned in its short axis, and is viewed from the apex. Note the separate nature of the right and left atrioventricular junctions, with the aorta interposing between the mitral valve and the septum. The leaflets of the aortic and mitral valve are in fibrous continuity in the roof of the left ventricle, with the area of fibrous continuity (*red dotted line*) thickened at both ends to form the right and left fibrous trigones (*cross-hatched ovals*). The right trigone is continuous with the membranous septum, forming the central fibrous body. The double-headed arrow shows the area of overlapping of the atrial and ventricular walls between the off-set hinges of the mitral and tricuspid valves (see Fig. 27-3).

two muscular masses. In effect, this produces a sandwich of muscular and fibro-fatty tissues that interposes between the cavities of the right atrium and the left ventricle. In the past, we thought this was a true septum,¹ but the presence of the insulating layer means that it is a sandwich, rather than a true septum (Fig. 27-3). The true septum is found antero-superior to this muscular area, and is the atrioventricular component of the fibrous membranous septum (Fig. 27-4).

Figure 27-3 So as to provide this cut, the heart has been sectioned in four-chamber plane immediately inferior to the area where the aortic root interposes between the mitral valve and the septum. The feature of this area, which previously we suggested was an atrioventricular muscular septum, is that the right atrial wall overlaps the crest of the muscular ventricular septum between the off-set hinges of the mitral and tricuspid valves. A layer of extracardiac fat, the continuation of the inferior atrioventricular groove, and carrying the artery of the atrioventricular node, interposes between the muscular layers, so that the area represents a sandwich rather than a true septum.

Figure 27-4 In this heart, the cut, in four-chamber plane, is through the aortic root, in the area where the root lifts the mitral valve away from the septum (see Fig. 27-2). The section, in four-chamber plane, shows how the attachment of the septal leaflet of the tricuspid valve divides the membranous septum into atrioventricular and interventricular parts. The fibrous atrioventricular part is the only true atrioventricular septal structure.

As already emphasised, this structure, together with the interventricular membranous septum, is an integral part of the central fibrous body, and forms the rightward wall of the left ventricular outflow tract (see Fig. 27-2).¹⁷ It interposes between the subaortic outflow tract and the chambers of the right part of the heart. Because of its wedged position, the subaortic outflow tract in the normal heart also interposes between the mitral valvar orifice and the septum. In contrast, in the inlet to the right ventricle, one of the leaflets of the tricuspid valve is adherent to the ventricular septum over a considerable area. This anatomy is pertinent to the naming of the leaflets of the normal valves. In the mitral valvar orifice, the curtain of leaflet tissue is divided by an obliquely orientated solitary line of apposition into a short and square leaflet, best termed the aortic leaflet, but often termed the anterior leaflet.¹⁸ The other leaflet is more extensive in terms of its circumferential attachment, but shallower. This is the mural, or posterior, leaflet. This mural leaflet is usually divided into a variable number of scallops, most often three. The paired left ventricular papillary muscles supporting the solitary zone of apposition between these leaflets are positioned obliquely within the ventricle, occupying infero-posterior and supero-anterior locations (Fig. 27-5). The normal tricuspid valve has three leaflets, which are located in antero-superior, septal, and inferior or mural positions. The zone of apposition between septal and antero-superior leaflets is supported peripherally by the medial papillary muscle. From this small muscle, the extensive antero-superior leaflet, hanging from the supraventricular crest to separate the inlet and outlet portions of the right ventricle, reaches across to the large anterior papillary muscle, which in many hearts supports the middle portion of the leaflet. When the anterior muscle supports the end of the zone of apposition with the mural or inferior leaflet, the latter leaflet extends to the inferior papillary muscle,

Figure 27-5 The cartoon shows the short-axis section of the ventricular mass as viewed from the cardiac apex. The silhouettes of the mitral and tricuspid valvar orifices are marked by the red rings, with the positions of the papillary muscles superimposed as cross-hatched ovals. Note that, although the muscles supporting the mitral valve are usually described as being postero-medial and antero-lateral, when described according to the coordinates of the body, they are positioned antero-inferiorly and postero-superiorly. They support the two ends of the solitary zone of apposition between the leaflets of the mitral valve.

which is frequently indistinct. Then, between the inferior and the medial papillary muscles, numerous small muscles and tendinous cords anchor the septal leaflet of the tricuspid valve directly to the muscular septum. The final feature worthy of emphasis so as to provide the background for understanding the consequences of deficient atrioventricular septation in the setting of a common atrioventricular junction relates to the structure of the ventricular mass. In the normal heart, the distance from the attachment of the mitral valve at the crux to the ventricular apex, or the inlet dimension, is much the same as that from the ventricular apex to the antero-superior attachment of the leaflets of the aortic valve, this being the outlet dimension (Fig. 27-6). As we will see, there is marked inequality of these dimensions in the abnormal hearts.

Figure 27-6 The heart in this image has been sectioned in parasternal long-axis plane, showing the dimensions of the ventricular mass (double-headed arrows). Note that, in the normal heart, these inlet and outlet dimensions are equal.

Basic Morphology of Atrioventricular Septal Defects

The essential morphological ingredient of the hearts we describe here as having atrioventricular septal defects is the presence of a common atrioventricular junction.^{15,19} Part and parcel of this arrangement is the abnormal formation of the fibrous skeleton of the heart. The fibrous skeleton can only be seen in anatomical specimens, and cannot, as yet, be imaged clinically. The overall structure of the junctional arrangement, in contrast, can readily be identified. It is either common to all four cardiac chambers, or it is not. There are no intermediate, or transitional, arrangements. In the normal heart, as already illustrated, there are separate right and left atrioventricular junctions (see Fig. 27-1). This goes hand in hand with the presence of a normal fibrous skeleton, the essence of the normal skeleton being the fusion of the right fibrous trigone with the membranous septum to form the central fibrous body. This arrangement is, of necessity, fundamentally disturbed when there is a common atrioventricular junction (Fig. 27-7).

Because of this fundamentally different junctional architecture when compared to the normal arrangement (see Fig. 27-2), there are significant departures from normality in at least four of the features enumerated above as characteristic for hearts with separate right and left atrioventricular junctions. First, almost always, but not universally, there is a defect at the anticipated site of the structures which usually interpose between the right atrium and the left ventricle. These structures are the muscular atrioventricular sandwich and the membranous atrioventricular septum. The septal deficiency is comparable irrespective of whether there is a common valvar orifice within the common junction (Fig. 27-8), or separate atrioventricular valvar orifices for the right and left ventricles (Fig. 27-9),

Figure 27-7 This specimen, from a patient with atrioventricular septal defect with common atrioventricular valve, has been sectioned in the short axis of the ventricular mass and photographed from the ventricular apex (compare with Fig. 27-2). Note the commonality of the atrioventricular junction, with the subaortic outflow tract now squeezed between the junction and the superior ventricular wall. The site of fibrous continuity between the aortic and common atrioventricular valves is marked (red dotted line), along with the positions of the fibrous trigones (red cross-hatched areas). There is no formation of a central fibrous body. Note also the changed location of the papillary muscles supporting the left ventricular component of the common atrioventricular valve (red circles). The mural leaflet of the left component of the valve guards less than one-third of the circumference of the left half of the common atrioventricular junction (white lines).

Figure 27-8 This specimen, from a patient with atrioventricular (AV) septal defect and common atrioventricular valve, is photographed from the right side. Note the common atrioventricular junction (bracket), and the septal defect (star) between the leading edge of the atrial septum and the scooped-out crest of the ventricular septum.

Figure 27-9 In this heart, with a so-called ostium primum defect, the septal deficiency (star) is again between the leading edge of the atrial septum and the scooped-out crest of the muscular ventricular septum, but in this instance because the leaflets that bridge between the ventricles are not only fused to each other, but are also fused to the crest of the muscular ventricular septum. The phenotypic feature is the common atrioventricular (AV) junction (bracket).

this latter arrangement, of course, also being known as the ostium primum defect. The septal deficiency exists because of lack of contiguity between the leading edge of the atrial septum and the crest of the muscular ventricular septum.

Figure 27-10 The cartoons show the difference in structure of the fibrous skeleton when there is a common atrioventricular junction (*right hand panel*), as opposed to separate right and left atrioventricular junctions (*left hand panel*; see also Figs. 27-2 and 27-7). The membranous septum is fused with the right fibrous trigone to produce the central fibrous body when there are separate junctions.

The second feature is the ovoid shape of the common atrioventricular junction. Irrespective of the number of atrioventricular valvar orifices within the junction, the left ventricular outflow tract is no longer wedged between the left and right atrioventricular orifices, as is seen in the normal heart (see Fig. 27-2). Instead, the aortic orifice is antero-superior to the common junction. Although there is still fibrous continuity between the leaflets of the aortic and atrioventricular valves, and although the ends of this area of fibrous continuity are strengthened to form left and right fibrous trigones, the morphology of the trigones cannot be compared with those found in the normal heart (compare Figs. 27-2 and 27-7). Indeed, as we have already emphasised, the entire fibrous skeleton differs fundamentally from the normal arrangement (Fig. 27-10). The right trigone may, at times, interpose between the left ventricular outflow tract and the right atrium. It may also be part of an abnormal atrioventricular fibrous septum.²⁰ It is in a different location, nonetheless, from the normal right trigone.

Since there is a common atrioventricular junction, and a lack of any septal atrioventricular muscular contiguity, the third feature that differs from the normal is the arrangement of the valvar leaflets that guard the common junction. These leaflets, irrespective of whether they guard a common atrioventricular orifice or separate orifices for the right and left ventricles, bear scant resemblance to the arrangement of the leaflets of the normal mitral and tricuspid valves (see Fig. 27-5). When describing the valves, and comparing them with the arrangement seen in the normal heart, it is important to state how we distinguish the boundaries of the individual leaflets. Joseph Hyrtl, the eminent Viennese anatomist of the 19th century, showed great prescience when he commented that the mitral valve came into the heart like a devil into the baptismal font.²¹ To avoid the semantic problems that have complicated previous definitions, we distinguish between several significant aspects of atrioventricular valves when making our own choices. First, we assess the nature of the junction that they guard separately from the precise origin of their hinge points, since the latter are not always being concordant with the

junction. We then distinguish both of these features from zones of apposition between the parts of the valve as seen in closed position. It is this latter feature we then use as the arbiter of the number of leaflets within the overall curtain of valvar tissue,¹⁸ rather than seeking to distinguish the gaps between the leaflets on the basis of their chordal support.²² The nature of the cordal support, of course, is also of importance, but this is yet another feature of which we take note. This feature, however, is insufficiently discrete to act as the criterion for the boundaries between the leaflets. Furthermore, the cordal arrangement is best seen when the valve is open, whereas the leaflets subserve their most important function, namely to prevent valvar regurgitation, when in their closed position. It makes most sense to us, therefore, to assess their boundaries when seen in their closed position.²³ When studied in this suggested fashion, the overall curtain of leaflet tissue in hearts having the phenotypic feature of an atrioventricular septal defect with common atrioventricular junction can be separated into five discrete components (Fig. 27-11). These five leaflets, seen to their best advantage when the common junction is guarded by a common valvar orifice (Fig. 27-12), can be arranged so as to provide separate orifices within the common junction for the inlets to the right and left ventricles. This latter pattern is achieved when a tongue of valvar tissue joins together the two leaflets of the essentially common valve that bridge the ventricular septum (Fig. 27-13). This tongue is usually attached also directly to the musculature along the length of the crest of the ventricular septum (see Fig. 27-9). It is not, therefore, analogous to the so-called annulus of the valve, which is typically part and parcel of both the atrioventricular junction and the fibrous skeleton. In the so-called ostium primum defect, the fused bridging leaflets are depressed into the ventricular cavity, and fused to the crest of the scooped-out ventricular septum (see Fig. 27-9).

A further fundamental difference from the normal situation is seen in the arrangement of the left ventricular papillary muscles. Paired muscles remain in the left ventricle but, instead of being located in antero-inferior and postero-superior positions (see Fig. 27-5), they are

Figure 27-11 The cartoon shows the basic arrangement of the leaflets to be found in the valve guarding the common atrioventricular junction. The black dotted lines show the plane of the ventricular septum, while the double-headed arrow shows the zone of apposition between the leaflets that bridge the ventricular septum. The valve is shown as seen from the cardiac apex, looking up the barrels of the ventricles.

Figure 27-12 This heart with common atrioventricular valvar orifice has been prepared by removing the atrial musculature, along with the arterial trunks. It is photographed from the atrial aspect. Note the common atrioventricular junction. The dotted line marks the zone of apposition between the bridging leaflets.

positioned in more or less direct supero-inferior position (see Fig. 27-7). On occasion, they may be even more abnormally arranged. The superior muscle may be located in a manner that compromises the left ventricular outflow tract. Alternatively, many small separate papillary muscles

Figure 27-13 This heart, representing the ostium primum defect, is prepared in the same fashion as the one shown in Figure 27-12. Note the tongue of valvar tissue joining together the two bridging leaflets. Apart from this feature, the two specimens are directly comparable. In particular, note that the dotted line marks the zone of apposition between the left ventricular components of the two bridging leaflets.

can be present, the muscles may fuse, or one muscle may be grossly hypoplastic or absent. It is these last arrangements that are usually described as the parachute arrangement.²⁴ In reality, the abnormal valve looks more like a funnel, representing the spatial inverse of a parachute.²⁵ A parachute constructed in this way would be a lethal device! The arrangement of the right ventricular muscles is comparable with the normal heart, being in medial, anterior, and inferior positions. The position of the medial papillary muscle, nonetheless, is itself variable, this variability reflecting the extent to which the superior leaflet bridges into the right ventricle.

The basic arrangement of the curtain of leaflet tissue guarding the common atrioventricular junction, therefore, is that of a valve with five leaflets (see Fig. 27-11). Three of the leaflets are confined to one or other of the ventricles, one being in the left ventricle and two in the right ventricle. The left mural leaflet, much less extensive than the mural leaflet of the normal mitral valve,²⁶ is tethered between the superior and inferior papillary muscles of the left ventricle. The antero-superior leaflet and the right mural leaflet are confined to the right ventricle. These leaflets retain to greater extent the pattern as seen in the normal tricuspid valve, although the antero-superior leaflet is of variable size, being reciprocal to the extent of bridging of the superior leaflet into the right ventricle. This bridging leaflet, and its facing partner positioned inferiorly, have no counterpart in the normal heart. They are tethered so as to extend between the cavities of the left and right ventricles, being anchored across the septum, albeit in some cases to a limited extent. In many instances, they are firmly attached to the septal structures at their point of crossing. Since they extend across the ventricular septum, they can appropriately be

Figure 27-14 The left atrioventricular valve in this heart with common atrioventricular valvar orifice is photographed by the surgeon in the operating room, and is shown in surgical orientation. Note the trifoliate pattern of valvar closure (*dotted lines*). (Courtesy of Dr Benson R. Wilcox, University of North Carolina, Chapel Hill.)

called bridging leaflets. The space between them is their zone of apposition. This zone of apposition was rightly compared to so-called commissures found in the normal mitral and tricuspid valves.²⁷ Describing the appositional zone as a commissure, however, can be contentious, and creates unnecessary problems with the need to distinguish this structure from a so-called cleft. Arguments about the commissural or non-commissural nature of the space between the left ventricular components of the bridging leaflets also conceal the fact that it is, unequivocally, a zone of apposition between them. Indeed, because of this, the left valve closes in trifoliate fashion (Fig. 27-14). Such closure is markedly different from the pattern of closure of the mitral valve, the two leaflets of which come together along a solitary zone of apposition. If the aortic leaflet of the normal mitral valve is cloven artificially, then the space thus created extends into the subaortic outflow tract, as do congenital clefts of the otherwise normal mitral valve (see Chapter 35). The zone of apposition between the left ventricular components of the bridging leaflets, irrespective of how it is named, is part of the orifice between left atrium and left ventricle. It has no morphological affinity with clefts seen in the aortic leaflet of the otherwise normal mitral valve (see Chapter 35). As we will discuss, almost always nowadays the surgeon will close the space as part of the operative repair, but this surgical manoeuvre never produces an arrangement of leaflets for the new left atrioventricular valve that replicates the arrangement seen in the normal mitral valve (see Fig. 27-2).

The fourth difference in morphology that characterises an atrioventricular septal defect with common atrioventricular junction is found in the architecture of the ventricular mass. In the normal heart, the inlet and outlet dimensions of the left ventricle are approximately the same (see Fig. 27-6). In atrioventricular septal defects

Figure 27-15 In this heart with atrioventricular septal defect and common atrioventricular junction, the valvar leaflets have been stripped away from the ventricular base. Although this reveals the extent of disproportion between the inlet and outlet dimensions of the ventricular mass, and shows the extent of scooping of the ventricular septum, there is no way of knowing whether the heart initially had a common valvar orifice, or separate valves for the right and left ventricles within the common junction. (Courtesy of Professor Anton E. Becker, University of Amsterdam, Amsterdam, The Netherlands.)

with common junction, the dimension of the outlet is considerably greater than that of the inlet (Fig. 27-15). It is of little consequence morphologically whether this is because the inlet is shorter than normal, or because the outlet is longer. Probably it is a combination of the two. Irrespective of such niceties, the disproportion between inlet and outlet dimensions is readily apparent (see Fig. 27-15). More significantly, it is within the same range be there a common orifice within the overall curtain of valvar tissue, or separate valvar orifices at the inlets to the right and left ventricles (Fig. 27-16).²⁶ Indeed, once the curtain of valvar leaflets is removed from the atrioventricular junctions in any individual heart, it is not possible to judge simply from examination of the ventricular mass whether there had initially been a common valvar orifice or separate right and left atrioventricular orifices (see Fig. 27-15).¹ When large numbers of hearts are studied, nonetheless, the extent of deficiency of the mid-point of the septum,

Figure 27-16 The graph shows the measurements of the ventricular inlet as a ratio of the outlet in a large series of hearts in the archive of Children's Hospital of Pittsburgh. The proportions do not vary significantly between hearts having a common valvar orifice as opposed to separate valves for the right and left ventricles, although there is a greater degree of scooping in presence of a common valvar orifice.

which we describe as the degree of scooping, is usually greater in those hearts having a common atrioventricular valvar orifice.²⁸

Categories of Atrioventricular Septal Defect

All the lesions falling within the group to be discussed in this chapter are unified by presence of a common atrioventricular junction. Although the individual internal structures of the hearts unified in this fashion can differ widely, clinicians recognise two major categories, often considered to be partial and complete. There are two aspects of the underlying anatomy underscoring these differences in clinical stratification. The first is the arrangement of the individual leaflets within the overall curtain of valvar tissue guarding the common atrioventricular junction. The second is the relationship between the bridging leaflets of the common valve and the atrial and ventricular septal structures. There are problems in seeking to combine these two features so as to identify presumed complete and partial variants, since the two aspects of anatomy are mutually independent. It has been attempts to combine description of the two features to give one all-embracing categorisation that has produced the bewildering array of definitions for so-called transitional or intermediate lesions. By describing the two features separately, we avoid the need to nominate intermediate categories. Other features, nonetheless, are important in categorisation. Examples are the sharing of the common atrioventricular junction between the atrial and ventricular chambers, and the presence of associated lesions. All of these features require description.

Arrangement of the Valvar Leaflets Relative to the Atrioventricular Orifices

In all hearts having the phenotype of atrioventricular septal defect with common atrioventricular junction, the curtain of valvar tissue guarding the junction can be described in terms of five leaflets (see Fig. 27-11). On the basis of the anatomical relationship between the two bridging leaflets, all of these hearts can be placed into one of two groups, with no intermediate categories. The majority have a space between the two bridging leaflets and, hence, have a common atrioventricular valvar orifice (see Fig. 27-12). The component of this common valve committed to the left ventricle almost always closes in trifoliate pattern, with zones of apposition between the left mural leaflet and the left ventricular components of the superior and inferior bridging leaflets, and a further zone of apposition between the bridging leaflets themselves (see Fig. 27-14). Within this arrangement, the mural leaflet guards less than one-third of the left component of the common junction.²⁶ It is not possible for the surgeon to restore the anatomy of the normal mitral valve simply by closing the zone of apposition between the left ventricular components of the bridging leaflets.

In some of the hearts fulfilling the criterion for inclusion within the overall anatomical group, the two bridging leaflets are themselves joined to each other by a connecting tongue of valvar tissue. This divides the common atrioventricular junction into right and left components (see Fig. 27-13). In most instances, shunting across the defect

in this setting is confined at atrial level, since the leaflets are also fused to the crest of the muscular ventricular septum (see Fig. 27-9). Such fusion to the ventricular septum, however, is not a universal feature of hearts in which the common junction is divided into right and left ventricular components by the union between the bridging leaflets. In some instances, the bridging leaflets can be fused to each other, thus dividing the valvar orifice, but also fused to the underside of the atrial septum so that the potential for shunting is restricted at ventricular level. Furthermore, in rare instances, the bridging leaflets can be fused so as to produce separate valvar orifices for the right and left ventricles even when the tongue of leaflet tissue joining the leaflets is well away from both the atrial and ventricular septums (Fig. 27-17). The presence of the hearts such as illustrated in Figure 27-17 shows that, in reality, the hallmark of the so-called partial defect is the presence of dual orifices within a common atrioventricular valve. When the valvar orifice is divided into separate components for the right and left ventricles, it is unusual to find a freestanding septal leaflet on the right side of the septum. Instead, in most instances, the right ventricular component of the inferior bridging leaflet is the only component that stands free, with the connecting tongue and the superior bridging leaflet usually confluent with the septal surface. When seen from the left side, these components often form a pouch that bulges to the right. In terms of the overall morphology of the curtain of valvar tissue, therefore, all hearts can be divided into those with a common atrioventricular valvar orifice guarding the common junction, and those in which the common junction is guarded by separate right and left atrioventricular valves for the right and

Figure 27-17 In this heart with atrioventricular (AV) septal defect and common atrioventricular junction (*bracket*), the bridging leaflets are fused to each other, producing separate valvar orifices for the right and left ventricles, but float freely within the septal defect, so that there is the potential for shunting at both atrial and ventricular levels.

left ventricles, respectively. This feature is an all-or-none phenomenon.

Potential for Shunting across the Atrioventricular Septal Defect

It is the potential for shunting across the septal defect that is probably the single most important anatomical variant that influences clinical presentation. The anatomical variability depends upon the relationship of the bridging leaflets, and of the connecting tongue, if present, on the one hand to the lower edge of the atrial septum, and on the other hand to the crest of the scooped-out ventricular septum. In most cases, the two bridging leaflets are not attached directly to either septal component as they bridge between the ventricles (Fig. 27-18B). In this arrangement, therefore, the potential exists for shunting at both atrial and ventricular levels, as it does even if fused bridging leaflets float freely within the septal defect (see Fig. 27-17). The extent of ventricular shunting then depends upon the proximity of the bridging leaflets to the ventricular septal crest. If the leaflets float freely, then there will be an extensive interventricular communication. In other cases, however, cords from the septal crest can tightly tether one or other leaflet, or both leaflets. Ventricular shunting can then be limited. Very rarely, in the presence of separate superior

and inferior bridging leaflets, both leaflets may be fused to the ventricular septal crest. Shunting will then only occur at the atrial level, even though there is a common valvar orifice. The arrangement in which the bridging leaflets are attached directly to the ventricular septum (see Fig. 27-18A) is more typically seen when they are additionally attached to each other by the connecting tongue so as to produce separate valvar orifices for the right and left ventricles. As discussed already, this produces the typical ostium primum defect (see Fig. 27-9). But as also emphasised, this feature is not universal. In a proportion of patients with separate right and left atrioventricular valvar orifices, the bridging leaflets may be attached to each other by the connecting tongue, but intercaval spaces beneath the tongue, and beneath the bridging leaflets, can permit small interventricular communications. It is also the case that, in rare circumstances (see Fig. 27-13), the leaflets and connecting tongue can float freely in the space between the septal components, leaving large communications at atrial and ventricular levels. Should, however, the bridging leaflets, and a tongue if present, be firmly attached to the undersurface of the atrial septum (see Fig. 27-18C), shunting will be possible only at the ventricular level. The heart itself, of course, will still exhibit all the features of an atrioventricular septal defect with common atrioventricular junction. The most distinctive feature will be a left atrioventricular valve that closes in trifoliate fashion. We now know that the tissue of the bridging leaflets can close entirely the septal deficiency. Such spontaneous closure produces a heart with a common atrioventricular junction, but lacking the opportunity for shunting across the pre-existing atrioventricular septal defect.³⁻⁵ In terms of overall shunting across the atrioventricular septal defect, therefore, the key feature is the relationship between the bridging leaflets and the septal structures, a feature which is independent of the arrangement of the valvar leaflets that guard the junction.

Abnormalities of the Left Atrioventricular Valve

It is, perhaps, the arrangement of the curtain of atrioventricular valvar tissue found guarding the left ventricular half of the common atrioventricular junction that is the single most obvious feature of hearts under discussion. The part of the curtain contained within the left ventricle closes in trifoliate fashion (see Fig. 27-14), with zones of apposition between mural, superior, and inferior leaflets. Apart from its residence within the morphologically left ventricle, the only anatomical affinities with the morphologically mitral valve are the fabric of the valve, and even this shows significant differences.²⁹ The left valve, like the mitral valve, nonetheless, is itself liable to be congenitally malformed. Presence of additional connecting tongues between the leaflets of the valve can produce dual orifices (Fig. 27-19). Rarely, such fusion of leaflets can produce a left valve with three orifices. The presence of these tongues of leaflet tissue extending between adjacent leaflets, usually between one of the bridging leaflets and the mural leaflet, and separating the orifice into subordinate compartments, can be compared to the way in which the connecting tongue itself divides the common orifice into separate right and left atrioventricular components (see Fig. 27-19). When a tongue produces dual orifices within the left valve, each orifice is usually related to one of the paired papillary muscles, which supports the

Figure 27-18 The cartoon shows how the potential for shunting across the atrioventricular septal defect (*double-headed arrows*) depends on the relationship between the bridging leaflets and the septal components. When attached to the crest of the ventricular septum (A), shunting is confined at atrial level. If the leaflets float (B), then shunting is possible at atrial and ventricular levels. If attached to the underside of the atrial septum (C), shunting can only occur at ventricular level, whereas if the bridging leaflets close the septal defect (D), then the heart has a common atrioventricular junction in the absence of the potential for shunting.

Figure 27-19 The cartoon shows how additional tongues of tissue (red) convert a common valve with common orifice (left hand panel) into a common valve with dual orifices (middle panel), and then into the situation in which the left atrioventricular (AV) valve has dual orifices (right hand panel). The tongue in the right hand panel is shown between the inferior leaflet and the mural leaflet, but tongues can also be found between the superior leaflet and the bridging leaflet, while further tongues can be found in the right component of the valve. Indeed, it is possible for the left valve to have three valvar orifices.

leaflets. Such dual orifices do not usually render the valve incompetent. The papillary muscles themselves can also be abnormal. Hypoplasia of one or other papillary muscle, or fusion of the muscles, produces an arrangement replicating a funnel, albeit usually, and misleadingly, described in terms of a parachute. In this entity, the orifice of the valve is, effectively, represented by the space between the bridging leaflets. In severe cases, the valve can take on a bifoliate configuration. Such a left valve with two leaflets remains anatomically different from the arrangement of the normal mitral valve. The superior papillary muscle can also be abnormally attached across the subaortic outflow tract and can then contribute to left ventricular outflow obstruction.

Rastelli Classification

In the past, it was conventional to subdivide atrioventricular septal defects with common valvar orifice depending on the morphology of the papillary muscle supporting the right ventricular extremity of the superior bridging leaflet. Such variability was first noted, and highlighted, by Rastelli et al.³⁰ They described three major types. In the first, which they dubbed type A, the bridging leaflet was mostly contained in the left ventricle, and was usually tightly tethered by tendinous cords to the crest of the ventricular septum (Fig. 27-20A). In this arrangement, the zone of apposition of the superior bridging leaflet with the anterosuperior leaflet of the right ventricle is supported by the medial papillary muscle, which arises in relatively normal fashion from the right side of the ventricular septum. In the second type, the superior bridging leaflet extends more into the right ventricle, usually being unattached to the ventricular septum as it crosses the septal crest but being supported by an anomalous right ventricular papillary muscle arising from the septomarginal trabeculation (see Fig. 27-20B). In the third type, the free-floating bridging leaflet, again unattached to the septum, extends even further into the right ventricle and is attached to an anterior papillary muscle (see Fig. 27-20C). In this spectrum, as the superior bridging leaflet becomes increasingly committed to the right ventricle, the zone of apposition with the anterosuperior leaflet of the right ventricle also moves into the right ventricle, with corresponding diminution in size of the anterosuperior leaflet. The spectrum can be extended, therefore, to include the so-called ostium primum defect.

In this lesion, of course, the bridging leaflets are usually fused to the ventricular septal crest, but with minimal bridging of the superior leaflet. Variability is also found in the arrangement of the inferior bridging leaflet. This relates not so much to the extent of bridging, since almost always the leaflet extends well into both ventricles, but more to its tethering. Sometimes, the leaflet is separated into right and left ventricular components by a well-formed raphe, which is firmly attached to the ventricular septum. In other hearts, the bridging leaflet is tethered by short tendinous cords as it crosses the septum, while in still others it can float freely. Thus far, no obvious relationship has been discovered between the degree of tethering of the two bridging leaflets. With recent refinements in the surgical technique for repair of the malformations, it is the degree of tethering of the leaflets that probably has more significance, so that increasingly the Rastelli classification itself³⁰ becomes more of historic interest.

Left Ventricular Outflow Tract

By virtue of its anterior and unwedged position, the left ventricular outflow tract is particularly susceptible to obstruction. This is true irrespective of whether there is a common valvar orifice or separate right and left atrioventricular valves within the common junction. On anatomical examination, the tract almost always seems narrowed. The length of the outflow tract, and the extent of the apparent narrowing, is more marked, nonetheless, in defects in which the superior bridging leaflet is firmly fused to the septal crest, in other words, in ostium primum defects.³¹ This apparent obstruction, however, is not reflected by pressure gradients measured prior to surgical repair. It is additional lesions compromising the already narrow channel that are responsible for haemodynamically significant obstruction or, alternatively, the effects of the surgery itself. The outflow tract, being largely muscular, has been shown to constrict during systole.³² Indeed, a systolic murmur can be present in these patients in the absence of atrioventricular valvar regurgitation. This might well be caused by the dynamic properties of the outflow tract. Such a murmur is probably a physiological finding. Any of the lesions that produce subaortic stenosis in the normal heart can rapidly produce similar problems in the setting of atrioventricular septal defects with common

Figure 27-20 The cartoon shows the essence of the Rastelli classification of variability in the superior bridging leaflet. Although not included by Rastelli et al,²⁰ it is now evident that the spectrum of malformation can be extended to include the ostium primum defect (*top left hand panel*). Then, depending on the commitment of the superior bridging leaflet to the right ventricle (*broad double-headed arrow*), there is a spectrum with reciprocal diminution in size of the antero-superior leaflet of the right ventricle (*narrow double-headed arrow*), as shown in panels **A** through **C**, which represent the types designated alphabetically in the original description.

atrioventricular junction, particularly when there is tethering of the superior bridging leaflet, or separate valvar orifices for the two ventricles. These lesions are septal bulging of a fibrous subaortic shelf or tunnel, anomalous insertion of left ventricular papillary muscles, and tissue tags. The tissue tags can take origin from the partially formed interventricular membranous septum, from the superior bridging leaflet, or from anomalous fibrous tissue around the septal defect. When flaccid, such tags can contribute to spontaneous closure of the defect,³³ potentially producing a common atrioventricular junction in the absence of any intracardiac shunts.

Dominance of Chambers

Most usually in atrioventricular septal defects, be there separate right and left atrioventricular valvar orifices or a common valvar orifice, the right and left components of the common atrioventricular junction are of comparable circumference, and the ventricles are then of similar size. This arrangement produces the so-called balanced form of defect. The common atrioventricular junction, nonetheless, can be committed in its larger part to the right ventricle, producing right ventricular dominance, or to the left, giving a dominant left ventricle. Right ventricular dominance is usually associated with clinically significant hypoplasia

or abnormality of the left ventricular and aortic structures, but most often with normal alignment between the atrial and ventricular septal structures. In the presence of left ventricular dominance, in contrast, it is the right ventricular and pulmonary arterial structures which are hypoplastic, typically in association with malalignment between the atrial and the muscular ventricular septal structures. Such hearts with atrioventricular septal malalignment then constitute part of a spectrum that extends to double inlet left ventricle, but through a common atrioventricular valve. In these variants, the ventricular septum no longer meets the atrioventricular junction at the crux, with important consequences for the disposition of the atrioventricular conduction axis.³⁴ A similar spectrum obviously exists when the right ventricle is dominant, with the extreme end of this spectrum being double inlet right ventricle with common atrioventricular valve. It may be difficult clinically to distinguish between the hearts with double inlet and a common valve and those with atrioventricular septal defect and right ventricular dominance. The clinical point of note will be whether the patient in question is suitable for biventricular as opposed to functionally univentricular surgical correction (see Chapter 32). It is important, therefore, to recognise the hypoplasia of one of the ventricles when the other ventricle is dominant, and to search for any malalignment of the septal structures, recognizing the implications

that such malalignment has for the disposition of the atrioventricular conduction axis.³⁵

The concept of chamber dominance can also be extended to include the atriums. When one of the atriums is dominant, the common atrioventricular junction is more or less equally shared by the ventricles, but is mostly connected to the dominant atrium. The only exit for the other atrium is then across the atrial component of the atrioventricular septal defect. This arrangement is often termed double outlet atrium, but this description is also applicable to hearts having absence of one atrioventricular connection and straddling of the other atrioventricular valve (see Chapter 33). This last entity, of course, should be distinguished from atrioventricular septal defect with common atrioventricular junction and imbalance of the chambers. The significant distinguishing feature is the presence of the common atrioventricular junction as opposed to the absence of one atrioventricular connection. In those with the common junction, surgical repair usually becomes feasible once the atrial septum is removed,³⁶ taking care, of course, to respect the landmarks to the conduction system when resecting the septum.

Associated Malformations

If not ruled out by its anatomy, any lesion must be anticipated to exist in hearts having an atrioventricular septal defect with common atrioventricular junction. We have already mentioned some of the more frequent, notably, obstructions within the left ventricular outflow tract, and those affecting the left atrioventricular valve. Additional deficiencies of the atrial septum are important, and are sometimes described in terms of common atrium. Common atrioventricular valves can also be found in hearts with abnormal segmental connections, such as double inlet ventricle, and discordant or ambiguous atrioventricular connections. In these settings, the patients can have concordant ventriculo-arterial connections, but they are found, much more frequently, with other ventriculo-arterial connections. Discordant ventriculo-arterial connections are the rule in association with either double inlet left ventricle or discordant atrioventricular connections. Double outlet from the right ventricle is frequently found particularly when there is isomerism of the atrial appendages (see Chapter 22). Of the other associated lesions, tetralogy of Fallot or pulmonary stenosis is particularly important, occurring in up to one-tenth of patients with atrioventricular septal defect and common atrioventricular junction. Presence of a second muscular ventricular septal defect is also significant. In those hearts with obstruction of the left ventricular outflow tract, right ventricular dominance, along with coarctation or interruption of the aortic arch, are to be expected.

Atrioventricular Conduction Tissues

When the atrial and ventricular septal structures are appropriately aligned, the atrioventricular conduction tissues have the same basic disposition. The arrangement is different from normal, but comparable in all types of atrioventricular septal defect with common junction.³⁷⁻³⁹ The fundamental difference from the normal arrangement reflects the lack of the atrioventricular septal structures,

Figure 27-21 The cartoon shows the basic disposition of the atrioventricular conduction tissues in atrioventricular septal defect with common atrioventricular junction and usual alignment of the septal components.

and the concomitant lack of a normal central fibrous body. The central fibrous body, of course, is the area of the normal heart where the atrioventricular node penetrates from the atrial musculature to become the atrioventricular bundle. In the hearts with common junction, because of the deficient atrioventricular septation, the inferior limb of the atrial septum usually makes contact with the ventricular septum only at the crux. It is at the crux, therefore, that the atrioventricular conduction axis usually penetrates (Fig. 27-21). In consequence, the entire nodal area is displaced posteriorly and inferiorly. Although a well-formed triangle can be seen at this location, this nodal triangle is not the same as the normal triangle of Koch. It does, however, continue to provide a guide to the site of penetration of the atrioventricular bundle. This area of union between the postero-inferior extremity of the ventricular septum and the atrioventricular junction is the most reliable guide to the position of the conduction axis. The insulating tissue of the atrioventricular groove is particularly well formed at the point of penetration of the conduction axis from atrium to ventricle. The landmark of union of the ventricular septum with the atrioventricular junction is to be found even when the coronary sinus is unroofed or opens to the left atrium.³⁴ It is also present when there is malalignment between the atrial and ventricular septal structures (Fig. 27-22).³⁵ Having taken origin from the atrioventricular node, either in the nodal triangle or along the inferior atrioventricular junction, the elongated non-branching bundle runs either on the crest of the muscular ventricular septum or to its left side, being covered by the inferior bridging leaflet. The bundle branches are then found more posteriorly than in the normal heart. Only the right bundle branch extends along the crest in the bare area found in the presence of a common orifice. In hearts with separate valvar orifices for the right and left ventricles, this part of the axis is covered over by the connecting tongue of leaflet tissue. This feature is of major surgical importance, since it permits sutures to be secured on the left side of the fibrous raphe, or within the bridging leaflets themselves,

Figure 27-22 When there is malalignment of the atrial septum relative to the muscular septum, the atrioventricular node is formed at the point where the muscular ventricular septum meets the atrioventricular junction.

without courting damage to the underlying conduction tissues. The left ventricular outflow tract, by virtue of its unwedged location, is unrelated to the conduction axis. This feature eliminates the risk of surgical damage compared with the normal heart should removal be attempted of the obstructing lesions.

Related Lesions

Having defined the anatomical hallmarks of atrioventricular septal defect with common atrioventricular junction, it is possible to highlight other lesions with some similar features, but which do not fit into the group as defined because they do not possess a common atrioventricular junction. This distinction is particularly important for the epidemiologist because, in the past, such lesions have often been described as atrioventricular canal defects. It is also important because some of the hearts described do, indeed, show evidence of deficient atrioventricular septation, albeit with separate atrioventricular junctions. The most obvious lesion falling into the category of deficient septation is the heart with a normally located subaortic outlet, but with absent or deficient atrioventricular component of the membranous septum (Fig. 27-23).² Such defects permit shunting from left ventricle to right atrium, but only because there are separate right and left atrioventricular junctions. They have a normally wedged subaortic outflow tract, and they are very rare.⁴⁰

Closely related are the hearts with separate right and left atrioventricular junctions and normally wedged aorta, but with direct shunting across a perimembranous ventricular septal defect into the right atrium because of anomalous attachment of the leaflets of the tricuspid valve (Fig. 27-24).⁴¹ It is the presence of a mitral valve guarding a discrete left atrioventricular junction that distinguishes them from atrioventricular septal defects with common atrioventricular junction. This distinction holds equally good for hearts having a perimembranous inlet ventricular septal defect and a cleft in the aortic leaflet of an otherwise normally structured mitral valve. This lesion, the so-called

Figure 27-23 The cartoon shows the essence of the Gerbode defect, which is a deficiency of the atrioventricular component of the membranous septum, but with separate atrioventricular junctions.

Figure 27-24 In this cartoon, we show how ventriculo-atrial shunting can also occur through a perimembranous ventricular septal defect when there is an associated deficiency of the septal leaflet of the tricuspid valve. The phenotypic feature of this lesion, however, is the presence of separate atrioventricular junctions.

isolated cleft, is often considered to be directly related to atrioventricular septal defects. It may, indeed, have some developmental affinities.⁴² The anatomical arrangements underscoring the two lesions, nonetheless, are quite different. The two are unequivocally distinguished when the separate right and left atrioventricular junctions are recognised in the setting of the isolated cleft.⁴³

It also used to be considered that hearts with straddling of the tricuspid valve had an atrioventricular canal-type of ventricular septal defect.⁴⁴ Again, the lesions with straddling and overriding of the tricuspid valve have some features in common with atrioventricular septal defect, namely, valvar leaflets that override the septum, and they do lack normal atrioventricular septal structures. The presence of separate right and left atrioventricular junctions, nonetheless, serves once more to distinguish the straddling right valve from the entity with common atrioventricular junction.

In summary, therefore, it is the presence of the common atrioventricular junction that is the anatomical hallmark of all the hearts with deficient atrioventricular septation that are to be discussed further in this chapter with regard to clinical diagnosis and treatment.

MORPHOGENESIS

In the past, the starting point when considering the morphogenesis of atrioventricular septal defects was usually the assumption that the atrioventricular endocardial cushions contributed markedly to the formation of the septal structures that are lacking in the malformed hearts, and also to the atrioventricular valvar leaflets.⁴⁵ It was because of these assumptions that endocardial cushion defect came to enjoy some popularity as a descriptive term. The concepts underscoring this approach do not bear rigorous examination, neither from the stance of embryological evidence, nor on the basis of the anatomy of the definitive lesions. It is very attractive to argue that complete failure of fusion of the endocardial cushions will result in the so-called complete defect. Partial failure of fusion could then, arguably, result in the ostium primum, or partial, defect and, in similar fashion, account for the cleft in the aortic leaflet of the mitral valve. But something much more fundamental must happen to produce the group of hearts under discussion. We have already seen how their anatomy differs from the normal state in far more respects than presence of a simple hole in the septum, coupled with a cleft in the aortic leaflet of the mitral valve. Indeed, the very fact that isolated clefts in the aortic leaflet of the mitral valve do exist, but have markedly different anatomy from the group under discussion, is additional strong evidence that the abnormal development is more than simple failure of fusion of the embryonic endocardial cushions.

It could well be that an initial failure of fusion of the cushions is the first step in the production of an atrioventricular septal defect. But the cushions do not go on to produce all the valvar leaflets together with the atrioventricular septal structures. Formation of the valvar leaflets is a very late developmental event. It occurs predominantly by undermining of ventricular myocardium, a fact well known to German embryologists and anatomists in the 19th century.^{46,47} Thus, the abnormal atrioventricular valvar leaflets found in atrioventricular septal defects with common atrioventricular junction will be produced and sculpted, in part, from the grossly abnormal ventricular mass. It is the abnormal architecture of the ventricles, specifically their junction with the atriums, which is the anatomical hallmark of this lesion. When searching for the mechanism that results in the development of a common atrioventricular junction, therefore, it is necessary to direct attention to the formation of the junctional regions. This is where it is

important to understand the initial function of the atrioventricular endocardial cushions. They act as the forerunner of the atrioventricular valves in early development, serving also to glue together the central point of the developing atrioventricular junctions. Only after the superior and inferior aspects of the junction have been stuck together can the aortic outflow tract be incorporated into the developing left ventricle (see Chapter 3). The leaflets of the mitral and tricuspid valves are then subsequently delaminated from the ventricular walls, or else sculpted in part from the fused cushions, but in the setting of a normally wedged subaortic outflow tract. If the endocardial cushions do not fuse together, or if there is an intrinsic abnormality in the formation of the atrioventricular junctions, this focal point for subsequent development of the ventricles is lost. The atrioventricular junctions will not grow as separate left and right components, with a septum and the subaortic outflow tract interposed between them. Instead, the superior and inferior margins of the junctions will spring apart, or else will retain their initial common appearance. The subaortic outflow tract will not then be incorporated appropriately into the developing left ventricle. It is the persistence of the initial common arrangement of the atrioventricular junction, therefore, which will produce the prototypic ventricular mass of an atrioventricular septal defect with common atrioventricular junction. The maldevelopment will also explain the presence of the basic septal defect itself. This is because, in the normal heart, the fusing cushions also provide the focal point for appropriate development and alignment of the atrial and ventricular septal structures. In the absence of such a keystone, the precise type of atrioventricular septal defect formed will then depend upon the way in which the atrioventricular valvar leaflets are delaminated, and developed, from the abnormal ventricular mass. In this respect, it should be remembered that a tongue of valvar tissue joins together the bridging leaflets in the ostium primum defect. Paradoxically, therefore, a lesion often presumed to develop because of failure of fusion of endocardial cushions has continuity of valvar tissue through the centre of the common junction. Consequently, although the initial insult resulting in an atrioventricular septal defect may well prove to be failure of fusion of the endocardial cushions, it is simplistic to suggest that the septal defect and valvar malformations all result from failure of the development of tissue derived from the atrioventricular endocardial cushions.

As yet, the tissues derived from the cushions have still to be determined with certainty. The abnormality, furthermore, involves more than the atrioventricular endocardial cushions themselves. Recent studies of developing mice show that other mesenchymal tissues around the embryonic primary atrial foramen are involved in its closure. These include a mesenchymal cap on the leading edge of the primary atrial septum, together with a mound of tissue, with its own mesenchymal covering, that grows into the heart from the posterior mediastinum. This latter structure, the vestibular spine, was discovered by His in 1880,⁴⁸ but disappeared from consideration for some considerable time before its recent resurrection.^{49–52} The vestibular spine, the primary atrial septum, and the endocardial cushions themselves, are all abnormal in mice with trisomy 16, which have deficient atrioventricular septation and a common atrioventricular junction.⁵³ Unlike the arrangement

as typically seen in humans, however, the trisomic mice have the common atrioventricular junction exclusively connected within the left ventricle, typically in association with abnormal ventriculo-arterial connections.⁵³ Further study of this mouse model,⁵¹ and other abnormal mice that have deficient atrioventricular septation,⁵² will undoubtedly clarify very soon the morphogenesis of atrioventricular septal defect with common atrioventricular junction. Such studies are also likely to identify the genes involved in normal and abnormal development. It will be necessary, nonetheless, to take careful note of the precise structure of the cardiac abnormalities produced in these experimental animals in order to make appropriate inferences for the situation pertaining in human maldevelopment.

PATHOPHYSIOLOGY

Atrial Shunting

There is almost always an atrial component of the defect, the so-called ostium primum defect, across which there is a left-to-right shunt. In about one-third of patients, even those with separate right and left atrioventricular valvar orifices, there is also a small right-to-left shunt. When the atrial septum is malaligned leftwards in relation to the common atrioventricular junction, a proportion of the systemic venous blood is directed into the left ventricle, and thus into the aorta. In those in whom the atrial septum is virtually absent, often described as common atrium, there is usually admixture of the systemic and pulmonary venous returns. This is largely because of the absence of a septum, but it is also, in part, because of the high incidence of anomalous venous connections, particularly in hearts from patients having isomerism of the atrial appendages. In the latter setting, with isomeric right appendages, the blood from a left-sided superior caval vein, if present, empties directly into the left upper corner of the atrium instead of flowing into the coronary sinus and thence into the right-sided atrium. The coronary sinus, of course, is absent in the setting of right isomerism, so perforce coronary venous blood must drain directly into the atrial cavities. As a result a mild degree of undersaturation is not uncommon in patients with right isomerism also having an atrioventricular septal defect.

Ventricular Shunting

If there is an unobstructed ventricular component to the defect, the direction of flow through it will depend upon resistance to outflow from the two ventricles. Subaortic stenosis, or aortic coarctation, will favour left-to-right shunting, whereas obstruction of the right ventricular outflow tract or pulmonary vascular obstructive disease will favour right-to-left shunting. When none of these complicating factors is present, the shunt is left-to-right, as in simple ventricular septal defect.

Ventriculo-atrial Shunting

Ventriculo-atrial shunting is a phenomenon that is found most typically in patients with deficient atrioventricular septation. In all those with a common atrioventricular junction, ventriculo-atrial shunting can occur during ventricular systole through the zones of apposition between

the bridging leaflets, should they be regurgitant. Such shunting is seen in more than half of all patients, irrespective of the valvar morphology. Significant shunting, however, associated with regurgitation across abnormal valves, is seen in a smaller proportion, perhaps one-fifth. The ventriculo-atrial shunting, best revealed with colour flow Doppler interrogation, usually tracks from left ventricle to right atrium. Right ventricular to left atrial shunting is uncommon, but when present adds to the arterial undersaturation.

Volume Loading

A left-to-right shunt at atrial level produces right ventricular volume overload, whereas a ventricular shunt in this direction primarily overloads the left ventricle. In patients with a common valvar orifice, volume overload of both ventricles is the rule. In those with a restrictive atrial component of the defect, left ventricular volume load will predominate, whereas restriction to left ventricular inflow will lead to a predominant right ventricular volume overload.

The leaflets guarding the common atrioventricular junction are often regurgitant, particularly in older patients, be there a common valvar orifice or separate ones for the right and left ventricles.⁵⁴ Such regurgitation can occur across either the left or right sides of the effectively common atrioventricular valve, but left-sided regurgitation is more important clinically because of its effect upon the systemic ventricle. This regurgitation, when present, produces further volume overloading of the ventricles. Although it is convenient, in order better to understand the pathophysiology, to separate the septal defects from valvar regurgitation, in reality the two are inseparable. For example, the regurgitant jet through the left atrioventricular valve is frequently directed toward the right atrium, thereby having a similar haemodynamic effect as a communication from the left ventricle to the right atrium. If there were such a thing as a pure shunt from left ventricle to right atrium in a patient with an atrioventricular septal defect, it would be obligatory, since it would not depend on pulmonary vascular resistance.⁵⁵ Excessive flow through the left and right components of the common atrioventricular junction occurs both because of the left-to-right shunts and because of the valvar regurgitation.

Pressure Loading

The right ventricular pressure is most commonly elevated because of an unobstructed ventricular component of the atrioventricular septal defect. Right ventricular hypertension, however, can also reflect increased left atrial pressure and pulmonary hypertension. This can be produced, for example, by an associated partition within the left atrium, or by left-sided malalignment of the atrial relative to the ventricular septum, with an associated obstructive interatrial communication. Such right ventricular hypertension is also seen in some patients with isolated atrial shunting, when there is a large left-to-right shunt and increased flow of blood to the lungs. Included amongst these patients will be those with stenosis of or regurgitation across the left atrioventricular valve. An alternative cause for pulmonary hypertension in this setting is the presence of an obligatory shunt from left ventricle to right atrium. This also produces, effectively, a large left-to-right shunt.

A raised pulmonary arterial pressure, therefore, is a feature of patients having atrioventricular septal defects with large ventricular components. In those with shunting exclusively at atrial or ventriculo-atrial levels, it is caused by high pulmonary blood flow, or obstruction to pulmonary venous return. Elevated flow to the lungs, and increased right ventricular pressures, are instrumental in the development of obstructive pulmonary vascular disease. This develops earlier than is usually the case for those having an isolated ventricular septal defect. It is now accepted that this tendency is further accentuated in the presence of Down's syndrome because of the susceptibility of such patients to obstruction of the upper airways and associated alveolar hypoventilation. This tendency to more rapid progression of pulmonary vascular disease is one of the reasons underscoring the trend to earlier surgical intervention for those patients with a common atrioventricular valvar orifice. Most centres would now elect to operate on such patients within the first 6 months of life.

PRESENTATION AND SYMPTOMATOLOGY

In the current era of routine screening of patients deemed at high risk, such as those with Down's syndrome, and increasing likelihood of prenatal diagnosis, the full clinical picture as described in this section is encountered in an ever decreasing number of patients. Patients with large ventricular components to the septal defect, severe left atrioventricular valvar regurgitation, significant left ventricular hypoplasia, or complicating associated lesions such as aortic coarctation, present with severe cardiac failure in early infancy. If the ventricular component was the only problem, there would be a latent period of 1 to 2 months occurring after birth but prior to presentation. Those with both ventricular and atrial components tend to present earlier, due to the more rapid increase in left-to-right shunting. In a number of infants, however, pulmonary vascular resistance remains high after birth, and they may present late due to a lack of symptoms in infancy. This is a documented risk in the setting of Down's syndrome. As a result of routine screening programmes for cardiac disease in these children, development of Eisenmenger's syndrome is nowadays rare. Patients without these complicating factors, typically those with separate atrioventricular valvar orifices and the potential for shunting exclusively at atrial level, often escape detection of their cardiac disease in infancy. They then present during childhood with an incidental murmur or, in those with a common atrium, with mild cyanosis. In rare instances, they may not present until adolescence or adult life.

CLINICAL FINDINGS

In those patients with separate atrioventricular valvar orifices and shunting confined exclusively at atrial level, the clinical findings are as expected for simple interatrial communications within the oval fossa (see Chapter 25). Consequently, infants and children are usually free from symptoms, although some may have recurrent chest infections. On auscultation, wide splitting of the second heart sound is the most characteristic feature, although, in infants and younger children, the split may not be fixed. An ejection systolic murmur, of grade 2 or 3, is typically heard,

being maximal at the upper left sternal edge. When there is a large right-to-left shunt, a mid-systolic rumble may also be audible at the lower left sternal edge.

In the presence of a common atrioventricular valvar orifice, or significant ventricular shunting, failure to thrive and signs of congestive heart failure are frequent during early infancy. These patients usually present within the first 3 months of life. Recurrent chest infections are also encountered. The typical findings on clinical examination are an undernourished infant with tachycardia, tachypnoea, and hepatomegaly. The praecordium is hyperactive, and a systolic thrill is sometimes palpated at the lower left sternal border. The first heart sound is accentuated, with the second sound being narrowly split, its pulmonary component having an increased intensity. Murmurs heard can vary markedly, from a short murmur graded at 2 out of 6, and a soft ejection systolic murmur at the mid-to-lower left sternal border in those with a large ventricular septal defect and elevated pulmonary vascular resistance, to a pansystolic murmur graded at 4 out of 6 due to ventricular shunting and heard at the same site. Not infrequently, a soft mid-diastolic murmur is heard at the left lower sternal edge or the apex, reflecting increased flow across the common atrioventricular valve.

These cardinal physical findings reflecting differences in the specific anatomy may then be modified by the presence of atrioventricular valvar regurgitation. This can produce symptoms of a large left-to-right shunt and congestive heart failure, even in an infant with shunting exclusively at atrial level. The valvar regurgitation will be associated with a pansystolic murmur heard maximally between the lower left sternal edge and the apex. In this setting, there may also be a prominent mid-diastolic apical murmur due to flow. Presence of associated malformations can further modify these findings. Cyanosis, for example, could reflect abnormal systemic venous drainage, common mixing at atrial level, or co-existing tetralogy of Fallot.

As indicated in the previous section, infancy is occasionally uneventful, particularly in those patients with Down's syndrome. The patient can then present later in childhood with Eisenmenger's syndrome. Such patients are cyanotic, and the systolic and diastolic murmurs noted above are usually reduced or absent. Such an absence of murmurs is less likely than in those with isolated ventricular septal defects, for example, because of the frequency of atrioventricular valvar regurgitation. Pulmonary valvar closure is even more accentuated, and the second heart sound may become single. An early diastolic murmur of pulmonary regurgitation may supervene.

In patients with very little shunting, clinical symptoms are limited to atrioventricular valvar regurgitation, which can become clinically manifest in adult life. The same goes in all probability for the very rare patients having a common atrioventricular junction but with intact septal structures.

INVESTIGATIONS

Chest Radiography

The heart and aortic arch are usually on the left. There is generalised cardiac enlargement in proportion to the volume overload of the two ventricles. Because of the frequent atrioventricular valvar regurgitation, the heart may be

enlarged even in the absence of a left-to-right shunt. The heart may be enlarged, therefore, even when there is severe obstruction in the right ventricular outflow tract or pulmonary vascular obstructive disease, or when the septal structures are intact. The pulmonary trunk is prominent, and the peripheral vasculature is engorged except in the presence of obstruction within the right ventricular outflow tract. High kilovoltage filtered beam chest radiography may show left bronchial isomerism. If this is discovered, then interruption of the inferior caval vein, common atrium, or both, should be suspected.

Electrocardiography

A highly distinctive pattern of abnormalities is usually evident from the electrocardiographic tracings. The P wave is usually normal, except in the presence of isomerism of the left atrial appendages, when a superior P wave axis is usually found. Prolongation of the PR interval is found in over nine-tenths of patients with common valvar orifice, and in almost three-quarters of those with separate right and left atrioventricular valvar orifices. The superiorly orientated frontal QRS loop is manifested by dominant S waves in leads III and aVF, and prominent R waves in aVR (Fig. 27-25). When the frontal QRS loop is displayed or constructed, it is seen to run counter-clockwise. The further the frontal axis is deviated upwards and to the right, the deeper the scooping of the ventricular septum, and the more likely there is to be a common valvar orifice.^{56,57} In nine-tenths of patients, the initial portion of the QRS loop is directed downward and to the right. This characteristic feature serves to distinguish patients with atrioventricular septal defects and common junction from those other lesions with a superiorly orientated and counter-clockwise frontal plane loop. Amongst this group, tricuspid atresia is easily distinguished by the lack of right ventricular forces in the precordial leads. In atrioventricular septal defects, a delay in right ventricular depolarisation is almost invariable, indicating right ventricular

volume overload. A qR pattern in the right precordial leads in the presence of an otherwise typical electrocardiogram suggests left ventricular hypoplasia. This feature also occurs in one-fifth of patients with common orifice without other complicating features. The superiorly orientated frontal axis frequently prevents left ventricular hypertrophy from manifesting itself on the precordial leads. Prolongation of the QRS interval occurs in three-fifths of patients with common orifice, and in nearly two-fifths of those with separate right and left valvar orifices.

Echocardiography

Cross sectional echocardiography should provide a complete morphological diagnosis in all children with common atrioventricular junction and atrioventricular septal defect. Although the recognition of the presence of an atrioventricular septal defect is usually quite easy, even for those inexperienced in the analysis of congenitally malformed hearts, the complete delineation of all the relevant features requires considerable skill and knowledge.

The start to a successful complete morphological diagnosis is knowledge of the cardinal anatomic features.¹⁵ Absence of the atrioventricular septum is not unique to those with atrioventricular septal defects, but some other features are. The disproportion between the inlet and outlet dimensions of the ventricular mass results in deviation of the plane of the left atrioventricular orifice and valve as seen in the views showing the ventricular short axis. As a consequence, the standard basal view through the short axis of the left ventricle will cut the left atrioventricular valve in an oblique fashion, while the standard parasternal long-axis view does not section the point of maximal opening of the valve. If the latter plane is obtained, part of the left atrioventricular valve appears to be floating in the left ventricular outflow tract.

The unwedged position of the aorta, together with the relatively elongated left ventricular outflow tract, produces

Figure 27-25 The frontal leads of these electrocardiograms display a variable leftward deviation of the frontal axis in four different patients, indicating variable depth of the scoop of the ventricular septum. The prolongation of the PR interval is also a typical feature of patients having atrioventricular septal defect with common atrioventricular junction.

Figure 27-26 These images are from a subcostal scan from a patient with separate atrioventricular orifices. Imaging starts in a subcostal four-chamber plane (A) depicting the right and left atrium (ra and la) the lack of off-setting of the atrioventricular valves, and a small atrial component of the defect. The transducer is tilted to show the aortic valve, which only appears when the left atrium is no longer in the imaging plane, indicating the unwedged position of the aortic root (B). Slight additional tilting (C) shows the gooseneck deformity of the left ventricular outflow tract (lvot), the superior (sbl) and inferior (ibl) bridging leaflets, and the tongue of tissue (*star*) connecting the bridging leaflets and separating the two orifices. Additional tilting (D) demonstrates the right ventricular outflow tract and the pulmonary trunk. All images are taken at the end of diastole. Ao, aorta; lv, left ventricle; pa, pulmonary trunk; rv, right ventricle; rvot, right ventricular outflow tract.

the classic gooseneck appearance of the left ventricular outflow tract, which is usually apparent only in angulated subcostal paracoronal planes. A standard view showing the four chambers together with the aortic root, erroneously referred to as five-chamber view, therefore, can never be obtained in a patient with an atrioventricular septal defect and common atrioventricular junction. The left side of the atrioventricular valve is trifoliate. This is easily seen in a subcostal paracoronal plane taken a little to the right of the one displaying the gooseneck. In practise, scans rather than planes will reveal all the features necessary for the diagnosis, the subcostal approach being the most informative (Fig. 27-26).

Colour flow Doppler interrogation complements the anatomical investigation by demonstrating the sites of intracardiac shunting, and the presence or absence of atrioventricular valvar regurgitation and pulmonary hypertension, as well as pin-pointing any obstructions within the ventricular outflow tracts. Pulsed and continuous wave Doppler are used for quantitative measurements. Interventricular shunting at very low velocity readily establishes any elevation of right ventricular pressures, but pulsed or continuous wave Doppler interrogation is needed to calculate the difference in pressures between the ventricles. As in patients with isolated ventricular septal defects, it is usually possible to estimate both the flow of blood to the lungs and pulmonary vascular resistance. A regurgitant jet across the right atrioventricular valve with high velocity may be the result of left ventricular to right atrial shunting (Fig. 27-27). This type of shunting is relatively common, and although readily appreciated in the presence of

a ventricular septal defect, may lead to the erroneous conclusion of right ventricular hypertension in those patients with shunting exclusively at atrial level, or after surgical closure of the defect.

Because patients with atrioventricular septal defects frequently have isomerism of the atrial appendages, it is important precisely to determine the atrial arrangement,

Figure 27-27 This systolic frame from a subcostal four-chamber image with colour flow mapping demonstrates shunting from left ventricle (lv) to right atrium (ra). The colour flow jet may be misinterpreted as right atrioventricular valvar incompetence. la, left atrium; rv, right ventricle.

Figure 27-28 Both of these four-chamber images show the classic appearance of an atrioventricular septal defect with separate atrioventricular valvar orifices and potential for atrial shunting only, the so-called ostium primum atrial septal defect. Subcostal four-chamber image (*left*) and apical four-chamber image (*right*). Both images are taken at the end of diastole. la, left atrium; lv, left ventricle; ra, right atrium; rv, right ventricle.

as well as the ventricular topology. Elevated pulmonary vascular resistance can usually be excluded by appropriate Doppler interrogation of the flow to the lungs.

Separate Valvar Orifices

Separate valvar orifices within a common junction are the consequence of a tongue of valvar tissue joining together the facing surfaces of the bridging valvar leaflets (see Fig. 27-26). Almost always there is an interatrial communication between the leading edge of the atrial septum and the crest of the ventricular septum, to which the bridging leaflets are usually connected. Consequently, there is absence of the normal off-setting of the leaflets, and no potential for ventricular shunting. Historically, such a lesion was called an ostium primum atrial septal defect, but since the shunting is across an atrioventricular septal defect, the disadvantages of this usage are obvious.

Standard four-chamber sections readily demonstrate the atrioventricular septal defect, limited on one side by the atrioventricular valvar apparatus, and on the other side by the leading edge of the atrial septum (Fig. 27-28). The other key diagnostic features are the trifoliate configuration of the left atrioventricular valve, well seen in the subcostal or high parasternal short-axis sections of the left ventricular inlet (Fig. 27-29), and the gooseneck-like elongation of the left ventricular outflow tract. This latter feature is best seen in subcostal long-axis sections of the left ventricle (Fig. 27-30). It is more prominent in hearts with separate right and left atrioventricular valves, where the attachment of the superior bridging leaflet to the ventricular septum accentuates the nature of the body of the goose (see Fig. 27-30). The skilled echocardiographer readily distinguishes the less common variants in patients having an atrioventricular septal defect with common atrioventricular junction, but with separate atrioventricular valvar orifices. When there is complete absence of any interatrial communication, and four-chamber sections demonstrate an interventricular communication opening to the inlet of the right ventricle, it is lack of off-setting between left and right atrioventricular orifices and, again, the trifoliate arrangement of the left atrioventricular valve that give the diagnostic clues (Fig. 27-31). This feature distinguishes those with an atrioventricular septal defect from others with an isolated perimembranous ventricular septal defect opening to the inlet of the right ventricle. Occasionally, a left atrioventricular valve with three leaflets may be the only manifestation of patients having an atrioventricular

Figure 27-29 This subcostal short-axis image of the left atrioventricular valve is from a patient with an atrioventricular septal defect with common junction and separate atrioventricular valvar orifices. The three leaflets are best visualised in a slightly angulated paracoronal plane, which as in this example is usually closer to the right ventricular outflow tract (rvot) view than to the left ventricular basal short-axis view. Compare with the right image of Figure 27-31. ibl, inferior bridging leaflet; ml, mural leaflet; rv, right ventricle; sbl, superior bridging leaflet.

Figure 27-30 This angulated subcostal paracoronal image shows well the body of the goose. The plane is almost comparable to that shown in Figure 27-26B, but has been obtained with slight clockwise rotation. Ao, aorta; lv, left ventricle; ra, right atrium; rv, right ventricle.

Figure 27-31 This image is from a patient with an atrioventricular septal defect with separate atrioventricular valve orifices and an intact atrial septum. There is only a potential for ventricular shunting, as is apparent from the left image, which also shows the lack of off-setting of the atrioventricular valves. The right image demonstrates the trifoliate configuration of the left atrioventricular valve in a right ventricular outflow tract (rvot) subcostal plane (see also Fig. 27-29). ibl, inferior bridging leaflet; la, left atrium; lv, left ventricle; ml, mural leaflet; ra, right atrium; rv, right ventricle; sbl, superior bridging leaflet.

septal defect with common atrioventricular junction, the atrial and ventricular septal structures being intact. Such patients may well present as having mitral regurgitation, with the true nature of their spontaneously closed atrioventricular septal defect not initially being recognised. The diagnostic echocardiographic hallmarks, however, are the same as for the other forms of atrioventricular septal defect.^{58,59} Other less common variants found with separate atrioventricular valvar orifices, such as common atrium and so-called double outlet left or right atrium (Fig. 27-32), are easily recognised in a complete echocardiographic examination.

Additional abnormalities of the trifoliate left atrioventricular valve are frequently encountered in patients having an atrioventricular septal defect and separate valvar orifices. Varying degrees of valvar regurgitation may occur, and often shunting may be from left ventricle to right atrium (see Fig. 27-27). Because of the presence of an

interatrial communication, significant enlargement of the left atrium is unusual, even in the presence of severe valvar regurgitation. The presence of a large interatrial communication also precludes demonstration of any gradient between the left atrium and left ventricle. The quantitative assessment of valvar stenosis, in that setting, cannot be made with Doppler echocardiography. Since stenosis usually is the result of morphologic variants such as dual orifice left atrioventricular valve, or marked hypoplasia or absence of the mural leaflet (Fig. 27-33), the recognition of these variants is of crucial importance. A dual orifice within the left valve is a well-recognised abnormality, in which colour flow Doppler may demonstrate two discrete profiles of flow across the left-sided atrioventricular junction. This diagnosis, nonetheless, can be difficult. A bifoliate arrangement can present with a single papillary muscle in the left ventricle, easily seen on the apical left ventricular short-axis section. Double orifice or bifoliate left atrioventricular valves should always be suspected in young infants presenting with marked enlargement of the right ventricle. Severe stenosis or hypoplasia of the left atrioventricular valve is associated with hypoplasia of the left ventricle. Abnormalities of the right atrioventricular valve are less

Figure 27-32 This apical four-chamber section is from a patient with separate atrioventricular orifices and so-called double outlet right atrium. This end-diastolic frame clearly shows the malalignment between the atrial septum and the muscular ventricular septum. The superior bridging leaflet is firmly attached to the right side of the ventricular septum, allowing no interventricular shunting. la, left atrium; lv, left ventricle; ra, right atrium; rv, right ventricle.

Figure 27-33 This subcostal angulated paracoronal view is from a patient with absence of the mural leaflet of the left atrioventricular valve. Although the left valve has a bifoliate appearance, it is clearly different from a normal mitral valve. This valve was supported by a single papillary muscle in the left ventricle. ibl, inferior bridging leaflet; pa, pulmonary trunk; rvot, right ventricular outflow tract; sbl, superior bridging leaflet.

Figure 27-34 These subcostal four-chamber and paracoronal sections show the variation in size of the interventricular communication below the inferior bridging leaflet. Images A1 and A2 are from a case with firm attachment of the inferior bridging leaflet to the crest of the ventricular septum, allowing no interventricular shunting under this leaflet. In the case depicted in images B1 and B2, a large ventricular septal defect is present beneath the inferior bridging leaflet (*star*). The *arrow* in B2 shows the attachment of the mural leaflet in the left ventricle. la, left atrium; lv, left ventricle; lvot, left ventricular outflow tract; ml, mural leaflet; ra, right atrium; rv, right ventricle; sbl, superior bridging leaflet.

Figure 27-35 These apical four-chamber (*left*) and subcostal paracoronal (*right*) images show a patient with limited potential for shunting under the superior bridging leaflet (sbl). The superior bridging leaflet is attached to a papillary muscle (pm) on the crest of the interventricular septum, the Rastelli type A variant. In the case demonstrated here, the superior bridging leaflet is also attached by multiple cords to the crest itself. There is a slight bulging (*star*) of the leaflet towards the right ventricle at end-diastole (*left*) becoming more pronounced in systole (*right*). la, left atrium; lv, left ventricle; ra, right atrium; rv, right ventricle.

frequent, although regurgitation from the right ventricle to the right or left atrium is commonly encountered.

Common Valvar Orifice

The typical echocardiographic features of an atrioventricular septal defect with a common valvar orifice are first identified in four-chamber sections. There are usually both interatrial and interventricular communications, albeit that the sizes of the components of the defect are variable. The right ventricle is often dilated, as significant shunting at atrial level is the rule. The attachments of the bridging leaflets to the crest of the ventricular septum are variable, as is the extent of their bridging. The inferior bridging leaflet, often best visualised in the subcostal four-chamber sections, is frequently attached by a midline raphe to the crest of the ventricular septum, precluding any interventricular shunting close to the crux (Fig. 27-34). It may, however, be free-floating, and then the ventricular component will

usually be evident throughout the length of the septum (see Fig. 27-34). Most variation in the size of the ventricular component, however, is seen beneath the superior bridging leaflet. This is demonstrated superiorly in subcostal paracoronal or parasternal four-chamber sections. The superior bridging leaflet may sometimes be firmly bound down to the septal crest, with no potential for shunting beneath it. This is rare. More commonly, the superior bridging leaflet is attached to a normally positioned medial papillary muscle, and is additionally attached by multiple cords to the crest of the septum (Fig. 27-35). In the four-chamber and subcostal paracoronal sections, the interventricular communication appears to be shielded by a pouch of valvar tissue, bulging towards the right ventricle during systole. There are then multiple interventricular communications through the intercordal spaces, the patterns of flow being recognised with colour flow Doppler (Fig. 27-36). This

Figure 27-36 This apical four-chamber section with colour flow mapping is from a patient with limited potential for interventricular shunting under the superior bridging leaflet. The systolic frame shows a small jet of interventricular shunting (arrow) and a larger jet of left ventricle to right atrial shunting (star). (Compare also with Fig. 27-27.) la, left atrium; lv, left ventricle; ra, right atrium; rv, right ventricle.

arrangement is often dubbed the Rastelli type A lesion. Occasionally, the pouch may contain accessory valvar tissue and, as in those with isolated ventricular septal defects, such a pouch may eventually seal the defect. The so-called Rastelli type B defect, in which the papillary muscles in the right ventricle supporting the zone of apposition between the superior bridging and antero-superior leaflets is positioned in an anomalous mid-septal position, may be hard to recognise, particularly when it is associated with a very deep scoop of the muscular ventricular septum or with accessory valvar tissue. The presence of the so-called Rastelli type C defect, in which the superior leaflet is free-floating, is readily appreciated on the subcostal paracoronal planes as well as in the apical four-chamber section (Fig. 27-37). Almost always the interventricular communication is then very extensive. This pattern is always seen in association with either tetralogy of Fallot (Fig. 27-38) or double outlet right ventricle, and is also frequent in those with Down's syndrome.

Figure 27-37 The subcostal four-chamber (left) and angulated paracoronal (right) images demonstrate a large defect under the superior bridging leaflet. The superior bridging leaflet is free floating, being attached to a papillary muscle (pm) well within the right ventricular chamber and having no connection with cords to the interventricular septum, the so-called Rastelli type C defect. (Compare with Fig. 27-38.) Ao, aorta; la, left atrium; lv, left ventricle; ra, right atrium; rv, right ventricle; sbl, superior bridging leaflet.

The other important diagnostic feature is again the trifoliate arrangement of the left component of the common atrioventricular valve, as demonstrated in short-axis sections of the left ventricular inlet. The elongated, or gooseneck, shape of the left ventricular outflow tract is less obvious than in those with separate right and left atrioventricular valvar orifices, and in those with the Rastelli A malformation, since the superior bridging leaflet is less well attached to the septal crest (Fig. 27-39).

Possible variations in the morphology of the left part of the atrioventricular valve, albeit less common than in defects with separate atrioventricular orifices, should always be excluded. If found, they may have major implications for surgical repair. Less common variants include virtual absence of the potential for interatrial shunting when the atrial septum meets the bridging leaflets of the common valve, and absence of any ventricular component when the bridging leaflets are firmly attached to the ventricular septum. This latter variant is difficult to distinguish echocardiographically, and is clinically indistinguishable from the patients having separate atrioventricular valves and shunting confined at atrial level.

Variants Found with Either Separate Valves or a Common Valvar Orifice

An extremely important variation, usually readily recognised in four-chamber sections, is ventricular imbalance. Left ventricular hypoplasia is commonly associated with obstruction of the left ventricular outflow tract, whatever its cause, and is easily identified on four-chamber (Fig. 27-40) and long-axis sections. Right ventricular hypoplasia, by comparison is often not immediately apparent on a single image section and usually associated with atrioventricular septal malalignment, often described as double outlet atrium. This has important implications for disposition of the conduction tissues (see Fig. 27-22). Proper identification of right ventricular hypoplasia requires acquisition of image scans (Fig. 27-41). The association of tetralogy of Fallot or double outlet right ventricle does not fundamentally change the features of the common atrioventricular junction.

Isomerism of the atrial appendages is frequently found (see Chapter 22). The morphologically right ventricle may be to the right or to the left of the morphologically left ventricle, giving either right hand or left hand ventricular topology. The left hand pattern may then give the

Figure 27-38 This subcostal image is from a patient with a free-floating superior bridging leaflet (Rastelli type C defect) and tetralogy of Fallot. The aorta is overriding the ventricular septal defect, which is thus limited on one side by the superior bridging leaflet and on the other side by the aortic valve. Ao, aorta; lv, left ventricle; rv, right ventricle; sbl, superior bridging leaflet.

impression of discordant atrioventricular connections (see Chapter 39). When there is isomerism of the atrial appendages co-existing with an atrioventricular septal defect, the identification of the right ventricle depends on the recognition of cords from the bridging leaflets inserting into

the septum, along with the coarse apical trabeculations. In contrast, no cords insert into the left ventricular surface of the septum, and the morphologically left ventricle has paired papillary muscles.

Obstruction of the left ventricular outflow tract may or may not be associated with hypoplasia of the left ventricle. It may be caused by a particularly deep scoop of the ventricular septum, in combination with firm attachment of the superior bridging leaflet, or may be due to accessory tissue tags or fibrous ridges. The two forms can be found separately or in combination, and are identified in apical or subcostal long-axis cuts (Fig. 27-42).

Three-dimensional Echocardiography

With the rapid development of three-dimensional echocardiography, atrioventricular septal defect is among the first congenital lesions in which its value has been demonstrated.^{60,61} The interest is not surprising, since many echocardiographers find the evaluation of patients with an atrioventricular septal defect extremely difficult when using cross sectional imaging. Although the obvious reason is a lack of understanding of the particular diagnostic features as described in our previous sections, three-dimensional technology does facilitate understanding. The three-dimensional representation demonstrates the common atrioventricular junction, the atrioventricular valvar leaflets, the unwedged position of the aortic valve, and the scoop of the muscular ventricular septum in a way that

Figure 27-39 These angulated subcostal long-axis sections are taken from a patient with Rastelli type A defect (*left*). The gooseneck malformation of the left ventricular outflow tract is readily appreciated. The gooseneck is far less apparent in the right image, taken from a patient with a Rastelli type C defect. See text for further discussion. Ao, aorta; lv, left ventricle; lvot, left ventricular outflow tract; rv, right ventricle.

Figure 27-40 These apical four-chamber sections are from two patients with ventricular hypoplasia. The image on the left clearly shows left ventricular hypoplasia, and in addition a (surgically created) common atrium (ca). The image on the right is from a patient with right ventricular hypoplasia, however, is hardly appreciated on this single apical four-chamber section. See Figure 27-41 for additional planes. ivs, interventricular septum; la, left atrium; lv, left ventricle; ra, right atrium; rv, right ventricle.

Figure 27-41 These images are from a subcostal scan in a patient with right ventricular hypoplasia. The scan starts with a subcostal four-chamber section (A) and continues by tilting the transducer ventrally. It is very hard to identify the interventricular septum in sections A and B, although it is very clear in the latter that the left ventricle is much larger than the right. Sections C and D show the interventricular septum (arrows) and the very large ventricular septal defect. The right ventricular outflow tract is the only part of the right ventricle that is well developed (D). Ao, aorta; la, left atrium; lv, left ventricle; ra, right atrium; rv, right ventricle; rvot, right ventricular outflow tract.

Figure 27-42 The image on the left is a subcostal long-axis section from a patient with a common atrioventricular valve orifice. It shows an obstructed left ventricular outflow tract due to a tissue tag (arrow). The image on the right is an apical long-axis plane from a patient with separate left and right atrioventricular valve orifices and a very deep scoop of the muscular interventricular septum. There is severe intrinsic narrowing of the elongated left ventricular outflow tract combined with abnormal connections of valvar tissue (star). Ao, aorta; la, left atrium; lv, left ventricle; rv, right ventricle.

cross sectional imaging in isolation cannot. The technique has huge potential, for the purposes of both diagnosis and teaching. With the present generation of echocardiographic equipment, however, maximal frame rates are limited, and the quality of the images is far inferior to those obtained using cross sectional equipment. The technique is thus not yet ready for routine use in infants and small children, although this is likely to change quickly, possibly even within the time taken for this book to proceed to production.

Doppler Interrogation

When investigating any patient with an atrioventricular septal defect, colour flow Doppler interrogation is used to demonstrate interatrial, interventricular, or ventriculo-atrial

shunting. Pulsed and continuous wave Doppler interrogation can be used to measure the drop in pressure across any interventricular communication, across the left or right ventricular outflow tract, and across the right atrioventricular valve. This last measurement allows an accurate estimation of the right ventricular and pulmonary arterial systolic pressures. It is important to be aware, however, that the velocity profile in the right atrium will not allow an accurate prediction of right ventricular systolic pressure if there is shunting from left ventricle to right atrium. In addition, Doppler interrogation shows clearly any valvar regurgitation, including the specific site of regurgitation when present. This is crucial for the surgeon, enabling attention to be focused specifically at this part of the anatomy.

Regurgitation can be quantified by measuring the surface area of regurgitant jets, and by investigating the flow

in the pulmonary veins. For infants and children, however, such quantification has its limitations. Measuring the surface area of regurgitant jets may be less reliable in children due to the obligatory use of different probes and settings of the machine in different age groups. Investigation of the flow in pulmonary veins is unreliable in the presence of unobstructed shunting at atrial level, where systolic back-flow in the pulmonary veins is rarely encountered, even in the presence of significant regurgitation. If backflow can be demonstrated within the pulmonary veins, nonetheless, regurgitation is certainly significant.

Magnetic Resonance Imaging

Resonance imaging provides images similar to those obtained by echocardiography, but at much greater expense, often necessitating anaesthesia in infants and small children. Skilful selection of appropriate sections, nonetheless, permits original sections to be obtained, notably those in the plane of the inlet part of the ventricular septum. These show well the relationships between the bridging leaflets and the septal structures, and permit quantification of the potential for shunting at ventricular level (Fig. 27-43). Four-chamber sections also illustrate particularly well the relationship between the bridging leaflets and the septal structures (Fig. 27-44), revealing any disproportion between the ventricles (Fig. 27-45), and demonstrating malalignment between the atrial and ventricular septums when present. The short-axis sections obviously illustrate the pathognomonic feature of the common atrioventricular junction. Volumetric measurements by magnetic resonance imaging are superior to those obtained using cross sectional echocardiography in demonstrating the degree of right or left ventricular hypoplasia. Some prefer magnetic resonance imaging to evaluate all the morphological aspects of atrioventricular septal defects, stating that its potential to define the anatomy is superior.⁶² Although this may be true for a selected group of adults, it is certainly not valid for infants and children.

Figure 27-43 This magnetic resonance image is orientated so as to be in the plane of the ventricular septum. A common valvar orifice is clearly seen where the superior bridging leaflet is free-floating, whilst the inferior bridging leaflet is somewhat tethered to the septal crest.

Figure 27-44 This magnetic resonance image displays a four-chamber section and shows the common atrioventricular junction with the bridging leaflets floating within the septal defect.

Figure 27-45 This magnetic resonance image, again producing a four-chamber section, shows malalignment between the atrial and ventricular septums. The asterisk indicates the crest of the ventricular septum. There is marked ventricular imbalance.

Magnetic resonance imaging can also be used to measure precisely the regurgitant fraction across leaking valves and to calculate effective shunting. There are two methods available for quantification of shunting using cine-imaging, namely the volumetric and the flow quantification techniques. Only the second approach, using the phase-contrast sequence, is applicable to those with atrioventricular septal defects, allowing calculation of the ratio of flows and the shunt fraction. This technique can be used as an adjunct to Doppler echocardiography. Clinical decisions can then be made based on the combination of Doppler estimates of pulmonary and systemic arterial pressure and calculation of the ratio of flows using magnetic resonance imaging.

Cardiac Catheterisation and Angiocardiography

The obvious indication for cardiac catheterisation is to measure the pulmonary vascular resistance prior to operative correction. In addition, pulmonary vascular reactivity can be tested. The haemodynamic abnormalities found will be as already documented, and will normally be indistinguishable from those of an atrial septal defect with or without an associated ventricular septal defect.

Nowadays, cross sectional echocardiography demonstrates everything that angiocardiography did in the past,

and more, and complementary non-invasive imaging techniques are readily available. Consequently, in almost all circumstances, there is no indication for cardiac catheterisation or angiography prior to surgery. This applies not only to young infants but also to older patients who have no evidence for elevated pulmonary vascular resistance. Even the brief discussion of angiography that follows, therefore, is mainly of historic interest.

The best-known angiocardiographic feature was also the one that proved so difficult to interpret, namely the gooseneck malformation. It is seen on the frontal projection of the left ventriculogram, and depends primarily upon the abnormal left ventricular origin of the aorta (Fig. 27-46). The body of the goose is produced by the abnormal parietal attachment of the left component of the common atrioventricular junction. It is seen in all types of atrioventricular septal defect with common atrioventricular junction, and is characteristically smooth in outline. The scooped-out interventricular septum, initially thought to produce the body of the goose, is seen only when the bridging leaflets are firmly attached to it, or in other words in those with shunting confined at atrial level.

Should angiography be needed, most information is provided by ventricular injections profiled in left and right anterior oblique projections, usually modified by caudocranial angulation. In left anterior oblique projections, whether there is a common valvar orifice or separate right and left valvar orifices, the left atrioventricular component of the valve is seen in diastole to arise from the expanded common atrioventricular junction. In the right anterior oblique projection of the normal heart, the area of the muscular atrioventricular sandwich is seen between the mitral and tricuspid valvar orifices. In atrioventricular septal defects, its absence is manifested by the bridging leaflets hanging down superiorly and inferiorly from the common atrioventricular junction.

Interventricular communications are shown directly on the four-chamber projection. When there is a right-to-left shunt at ventricular level, these signs may be seen on both right and left ventricular angiocardiograms. Adding caudocranial tilt to the left anterior oblique view profiles the atrial septum much better, and also elongates the otherwise foreshortened muscular ventricular septum. In general, the less foreshortening of the ventricular septum the better, because this increases the chance of demonstrating a second muscular ventricular septal defect and separating it from the atrioventricular septal defect. Lengthening of the subaortic outflow tract by caudocranial tilt also improves demonstration of obstruction within the outflow tract, whether it is due to a discrete shelf, a fibromuscular tunnel, or accessory valvar tissue.

NATURAL HISTORY

When we wrote the first edition of this book, discussions of natural history were pertinent, since arguments raged as to the justification of offering surgical repair to patients with Down's syndrome. This, in turn, was because, although some good outcomes had been reported for surgical repair, on the whole the overall results for operative treatment in 1987 were less than outstanding, and often did not match the observed findings of an expectant approach.⁶³ This has changed in recent decades. Surgical mortality is now expected to be close to zero in the best hands. Paradoxically, because Down's syndrome and co-existing atrioventricular septal defects with common atrioventricular junction are frequently encountered by fetal scanning, many parents now elect for termination of pregnancy. The number of infants undergoing surgical repair, therefore, has declined in many developed countries. In those being considered for surgical repair, nonetheless, the major feature remaining of note in

Figure 27-46 This classic left ventricular angiogram is profiled in the frontal projection. Dye fills the left ventricle, the aorta, and adjacent vessels, one of which is an aberrant left subclavian artery. The typical so-called gooseneck deformity is clearly visible. The slight difference in angulation of panels A and B shows the so-called septal annulus in A, produced by the attachment of the bridging leaflets to the scooped-out ventricular septum, and the parietal attachments of the leaflets of the left atrioventricular valve in B.

terms of natural history is the rapid onset of pulmonary vascular disease. Because of this, most centres opt for surgical repair in patients with common atrioventricular valvar orifice before the age of 6 months, with a tendency in some centres to undertake surgery within the first 3 to 4 months of life.

In patients with shunting only at atrial level, the natural history is similar to that observed in the setting of atrial septal defect. The history can, however, be made worse by atrioventricular valvar regurgitation, or less commonly stenosis, of the left atrioventricular valve. This feature necessitates earlier surgical repair, often during the first year of life. In uncomplicated cases, elective surgical repair is undertaken around 4 years of age, before the patients begin school. The only feature that might prompt earlier repair is the occurrence of frequent respiratory infections, or failure to thrive. A small cohort of patients, with exclusively atrial shunting, may escape detection until adolescence or adult life. For these patients, studies of natural history show that very few are well at the age of 40 years, usually because of the development of arrhythmias.⁶⁴

TREATMENT

Medical Treatment

Heart failure and associated respiratory infections need the usual pharmacological treatment (see Chapter 14). Acute administration of beta-blockers and inhibitors of angiotensin-converting enzyme has been shown to reduce the left-to-right shunt in the majority of infants, but there have been no reports of chronic use of such treatment. Infants who do not respond to medical therapy require surgical treatment. The argument for a prolonged trial of medical treatment before undertaking surgery is less strong than in isolated ventricular septal defect, since there is a strictly limited chance of spontaneous cure or reduction in the significance of the atrioventricular septal defect.

Surgical Treatment

Indications for Operation

With the exception of those rare patients with small septal defects and competent atrioventricular valves, the treatment for all patients with an atrioventricular septal defect will be surgical correction. Medical therapy with digoxin and diuretics serves to stabilise the patients with a large shunt and cardiac failure during early infancy. Feeding by gastric tube is sometimes necessary to provide adequate caloric intake. The only aim of medical therapy is to postpone surgery in symptomatic infants, preferably until the age of 6 months. In young infants with a very high pulmonary vascular resistance, oxygen is occasionally given continuously during the last weeks prior to surgery in an attempt to reduce the incidence of post-operative pulmonary hypertensive crises. As discussed, pre-operative assessment can now generally be achieved by echocardiography alone. Catheterisation is indicated only when there is strong echo-based evidence of severe pulmonary hypertension.

The age at which to perform surgical repair has tended to become lower over recent years, which is in keeping with the general tendency in paediatric cardiac surgery. There are no systematic studies, however, investigating the matter of timing thoroughly. Normally, in the absence of congenital cardiac disease, pulmonary vascular resistance drops, and

remains fairly constant after 1 month of age. In the presence of atrioventricular septal defect with interventricular shunting, resistance may increase in the year following the initial drop. In some infants, resistance may even never show the anticipated initial drop. This rise in pulmonary vascular resistance has served as a strong incentive to operate earlier in life. Recent cohort studies indicate generally that repair below a body weight of 5 kg, or an age of 6 months, is only possible at the cost of more complications and a higher rate of reoperation.⁶⁵ Severely symptomatic patients may benefit from earlier operative repair because of failure to thrive, and to prevent secondary changes accompanying a large shunt and/or severe atrioventricular valvar regurgitation. In these patients, the atrioventricular anulus may dilate as the result of the large shunt, and valvar tissue may fibrose at the site of regurgitation, factors that may well complicate a repair postponed too long.

Objectives of Surgical Correction

Surgical correction aims at closure of all septal defects in order to abolish shunting and subsequent pulmonary congestion. Evolving insight dictates closure of the zone of apposition between superior and inferior bridging leaflets at all times, unless specifically contraindicated. The policy not to close the zone when the valve is competent has resulted in large numbers of reoperations for valvar regurgitation. The most frequent contraindication to closing the zone of apposition is absence or hypoplasia of the left mural leaflet, whence closure of the zone would render the valve stenotic. When striving to achieve these primary goals, care should be taken to avoid two complications, namely damage to the atrioventricular conduction system, and obstruction within the left ventricular outflow tract.

Closure of the Septal Defect

The manner in which the defect is closed can have a profound effect on the subsequent architecture of the atrioventricular valvar complex, because defect and valve are inseparable parts of the three-dimensional anomaly of the abnormal common atrioventricular junction. The shape of the patch or patches, and the technique used for insertion of sutures, therefore, are of utmost importance not only for septal closure but also for post-operative valvar function (Fig. 27-47).

Methods of repair can be categorised classically as use of one or two patches for closure of the entire defect, presuming there are atrial and ventricular components to close. A further categorisation is whether or not bridging valvar

Figure 27-47 So as to avoid distortion of the valvar leaflets during surgical correction, the size and shape of the interventricular patch must be tailored to fit the defect precisely. Use of patches of inappropriate shape, shown as too wide or too deep, will distort the anatomy, which in these cases widens the zone of apposition of the bridging leaflets.

Figure 27-48 The cartoon shows the essence of the classic technique for surgical repair, whereby both bridging leaflets are cut in the plane of the ventricular septum, so as to expose its crest. The single patch is sutured to the right side of the ventricular septum, and thereafter the cut edges of the bridging leaflets are sutured together, sandwiching the patch between them.

leaflets are cut in order to expose the atrioventricular valvar annulus at the ventricular septal junction. The cutting of bridging leaflets can be applied to both the superior and inferior bridging leaflet, depending on their extent of bridging. A further variable is the provided by the possibility of attaching one or both bridging leaflets directly to the septal crest. Permutation of these strategies results in at least eight possible combinations of techniques:

- Using one patch, and cutting the bridging leaflets^{66,67} (Fig. 27-48).
- Using one patch, but leaving the bridging leaflets intact. This is only possible with minimal bridging of both bridging leaflets, and constitutes a numerically minor subset (Fig. 27-49).
- Using one patch in which a cut is made to accommodate one of the bridging leaflets. This is applicable should one of the bridging leaflets bridge minimally, as in the Rastelli A malformation (Fig. 27-50).
- Using one patch, having sutured the bridging leaflets directly to the ventricular septal crest^{68,69} (Fig. 27-51).
- Using two patches, and attaching the inferior bridging leaflet to the ventricular septal crest, while inserting a patch between the septal crest and the superior bridging leaflet, which is left intact⁷⁰ (Fig. 27-52).
- Using two patches, attaching the inferior bridging leaflet to the ventricular septal crest, while cutting the superior bridging leaflet (Fig. 27-53).
- Using two patches, and cutting the bridging leaflets⁷¹ (Fig. 27-54).
- Using two patches, leaving the bridging leaflets intact (Fig. 27-55).

All techniques have protagonists, and publications on all techniques exist. No systematic trial has been carried

Figure 27-49 The cartoon illustrates the situation where the septal crest is exposed naturally, because of a Rastelli A configuration of the superior bridging leaflet, whilst in this case the inferior bridging leaflet is bifid. The single patch can then be attached to the right side of the ventricular septum, following which the adjacent leaflets, or parts of them, are sutured together, sandwiching the patch between them.

Figure 27-50 The cartoon shows the situation where the inferior bridging leaflet bridges extensively and is not bifid. A cut is made into a single patch, to accommodate the inferior leaflet, while the minimally bridging superior leaflet can be sutured to the single patch. The superior part of the patch is then sandwiched between the superior and the antero-superior leaflet.

out so as to draw conclusions on their merits. Publication bias has it that usually only desirable results are published (Table 27-1). The major advantage of the technique using only one patch is the excellent exposure of the entire ventricular septal crest, so that suturing of the ventricular patch is made much easier. The major disadvantage is the valvar

Figure 27-51 The cartoon shows the method of suturing the bridging leaflets to the septal crest directly, in this case with pledgeted sutures. The single patch is then confined to the interatrial part of the defect.

Figure 27-52 In this cartoon, the situation is shown where the inferior bridging leaflet is sutured to the septal crest directly, in this case with pledgeted sutures. A smaller patch is inserted between the septal crest and the superior bridging leaflet, so as to avoid obstruction of the left ventricular outflow tract, and/or distortion of the valvar leaflets.

suture line. Where friable valvar tissue might tear, the suture line takes up tissue, promoting the possibility of disruption, particularly in the setting of post-operative endocarditis. Good exposure of the ventricular septal crest may counterbalance these drawbacks.

The attraction of suturing the bridging leaflets directly to the ventricular septal crest is the obvious simplicity of the procedure, because placement of the more difficult of the two patches is eliminated entirely.⁷² The potential

Figure 27-53 The cartoon shows the situation where the inferior bridging leaflet is sutured to the septal crest directly, in this case with pledgeted sutures. The superior bridging leaflet is cut so as to expose the superior part of the septal crest. A smaller patch is inserted between the septal crest and the cut edges of the superior leaflet. The patch is sandwiched between the two parts of the superior leaflet.

Figure 27-54 In this cartoon, we show the technique whereby both bridging leaflets are cut so as to expose the ventricular septal crest fully. Two patches are used, of which the ventricular patch is attached to the right side of the ventricular septum, whilst the valvar side of the patch is sandwiched between the cut edges of the bridging leaflets. The atrial patch then is attached to the latter suture line.

drawbacks are, first, the possibility of narrowing of the left ventricular outflow tract superiorly, and second, distortion of the valvar apparatus, particularly if the septal defect has depth, in which situation the leaflets have to be brought down considerably to reach the septal crest. Personal

Figure 27-55 The cartoon shows the technique in which neither of the bridging leaflets is cut, nor are they sutured directly to the ventricular septal crest. An interatrial patch is inserted and attached to the right side of the septal crest, which is exposed by gently retracting the bridging leaflets one at a time with a retractor. The bridging leaflets are sandwiched between the interatrial and interventricular patches.

communication from Benson Wilcox, who was the first to advocate this policy, makes it clear that he only employed this technique if the ventricular defect was not too deep.

The tissues of the valvar leaflets are rarely normal, and are often deficient. It is illogical in our opinion, therefore, further to reduce the amount of tissue available for repair. Above all, we feel it to be unnecessary, unless bridging of one or both leaflets is minimal, when these leaflets can

easily be sutured to the patch without having to be cut. Whether a single patch or two patches are to be used, therefore, should in our opinion depend on the anatomy of the individual bridging leaflets. Only when both inferior and superior leaflets bridge the septum extensively, seen most often in patients with Down's syndrome, is a two-patch technique warranted. In all other anatomical variants, when one or both of the superior and inferior leaflets do not bridge the septum extensively, a single patch can be used. This single patch then has to be incised to accommodate any leaflet that bridges extensively (see Fig. 27-50). So, instead of employing one or two patches dogmatically, our approach is not to cut leaflets unless it proves impossible to visualise the location of intended stitches, which is a highly unusual circumstance.

Patches can be fashioned from synthetic material, or from autologous or xenologous pericardium. Synthetic fabric is sturdy, but any rough texture to its surface can lead to haemolysis should it be impinged upon by a regurgitant jet. Even in the absence of clinically significant regurgitation, haemolysis can be so severe as to necessitate reoperation. Pericardium is always smooth and does not lead to haemolysis, so is preferable in our opinion. Above all, autologous pericardium is cheap, supple, and easy to use. Its use minimises distortion of the delicate valvar tissues. Autologous pericardium should be treated for 5 minutes in 0.2% glutaraldehyde in order to prevent distension and aneurysmal widening, specifically of the interventricular patch.⁷³ Our favourite operative technique is illustrated in Figures 27-56 to 27-63.

The size, and semilunar shape, of the interventricular patch are of the utmost importance in determining the future function of the left atrioventricular valve. This is because, subsequent to correction, the leading edge of the patch will constitute part of the hinge of both atrioventricular valves. When the patch is either too broad or too deep, the valve is likely to become regurgitant (see Fig. 27-47).^{74,75} The interventricular patch is ideally always slightly shorter than measured. The bridging leaflets are then brought

TABLE 27-1

RESULTS OF SURGICAL CORRECTION IN SELECTED SERIES

Figure 27-56 This operative picture, and those which follow (through Fig. 27-63), are from a patient aged 6 months, weighing 7.1 kg, and having a body surface area of 0.38 m², with Down's syndrome, elevated pulmonary vascular resistance, and additional obstruction in the left ventricular outflow tract produced by accessory valvar tissue. The series shows the view of the atrioventricular junction obtained by the surgeon working through the opened right atrium. A retractor is elevating the right ventricular lateral aspect of the common atrioventricular valve. In this heart, being empty due to the use of cardioplegia, the valvar leaflets are flaccidly lying in the junction. The left ventricle is on the small side, the diameter of the left part of the atrioventricular valve is 14 mm, which is the norm for the size of the patient. The mural leaflet, in keeping with the smallish left ventricle, is also very small with an angular annular size of around 45 degrees. The superior bridging leaflet crosses the ventricular septum only minimally, typical of the so-called Rastelli A configuration. The ventricular septal crest is bare.

Figure 27-57 The view obtained of the common atrioventricular valve. The ventricles have been instilled with saline so as to test for valvar competence. The zone of apposition between superior and inferior bridging leaflets does not leak in this situation. A stay suture indicates where these two leaflets could be sutured together.

together, a manoeuvre that almost always abolishes regurgitation. As discussed, when surgeons use only a single patch for closure of both atrial and ventricular parts of the defect, it may be necessary to incise the leaflets, depending on the extent of their bridging. Success then depends on the technique of suturing.⁷⁶ In skilled hands, nonetheless, use of a single patch can produce results that are equally as good as those achieved using two patches. We conclude, therefore, that it is probably less the technique, but rather

Figure 27-58 The autologous glutaraldehyde-treated patch is being sutured to the right side of the ventricular septum with a running monofilament suture. Staying on the right side of the ventricular septum avoids the conduction tissues. Cords from the right ventricle should remain on the right side of the patch.

Figure 27-59 The stay suture pulls the bridging leaflets superiorly, exposing the inferior part of the ventricular septum. The suture line is being carried towards the crux, which is facilitated in this particular case by the bifid nature of the inferior bridging leaflet.

Figure 27-60 The insertion and attachment by running suture of autologous glutaraldehyde-treated pericardial patch has been completed. A running monofilament mattress suture attaches the pericardial patch to the bridging leaflets.

Figure 27-61 The stay suture has now been knotted to attach the bridging leaflets together at the site of the patch. The position of the ventricular patch can be seen clearly. The zone of apposition has not been sutured in this case, because this would make the valve stenotic, due to the very small size of the mural leaflet. The size of the left atrioventricular valve is now 13 mm, which is only 1 mm too small for the size of the patient. This was tolerated well, without physiologic stenosis.

Figure 27-62 The atrial pericardial patch has now been inserted, also with running monofilament sutures. The antero-superior leaflet and the right half of the bifid inferior bridging leaflet have both been attached to the suture line joining the ventricular and atrial patches. The slight bulging of the atrial patch shows that the left atrium is being filled by pulmonary venous blood. Absence of leakage into the right ventricle indicates absence of any residual interventricular communication. The aortic suture line indicates removal of the obstructing tissues in the left ventricular outflow tract through the aortic valve.

the familiarity of the surgeon with it, which determines the result.

Avoidance of Conduction Tissues

It is the course of the suture line relative to the ventricular septum and the coronary sinus that is the critical factor in avoidance of the conduction tissues. On the inferior side, the septal aspect of the mouth of the coronary sinus is a useful surgical landmark with which to predict the position of the atrioventricular node and the penetrating bundle³⁹ (Fig. 27-64), albeit that this loses its value when there is malalignment between the atrial and ventricular septums, or when the coronary sinus opens within the left atrium. As we have discussed, the triangle of Koch as such does not exist in atrioventricular septal defect, so only the coronary sinus and the cardiac crux point to the position of the atrioventricular node. Indeed, as emphasised, should there be

Figure 27-63 Injection of saline into the right ventricle shows that there is no leakage of the right atrioventricular valve. Post-operatively, this patient required ventilation with nitric oxide and delivery of sildenafil to decrease pulmonary vascular resistance. The patient was monitored by means of lines to measure left atrial and pulmonary arterial pressures.

malalignment rightward of the ventricular septum, then it is the point of union between the ventricular septum and the atrioventricular junction that marks the location of the atrioventricular node (see Fig. 27-22).

There are two possible placements of surgical suture lines that permit avoidance of the conduction tissues. The first is to stay on the right side of the ventricular septum, and the coronary sinus, leaving the sinus to drain into the left atrium (see Fig. 27-64). The resulting small right-to-left shunt is clinically irrelevant. This suture line takes a wide curve around the site of the atrioventricular node, permitting relatively wide margins for stitches. As this suture line takes an inferior route around the coronary sinus, the atrial patch has to be of a shape and size so as to accommodate for that extension. The alternative line is on the left side of the ventricular septum and the atrioventricular node, calling for shallow bites so as not to impinge upon the non-branching bundle, particularly beneath the inferior bridging leaflet, or the connecting tongue in those with separate valvar orifices. When using this suture line, a somewhat smaller atrial patch can be inserted, because the coronary sinus stays on the right side. When the septal crest is devoid of fibrous tissues that can serve as safe points for anchorage of sutures, this route places the branching bundle and its left fascicles in greater danger, so that those using this approach should take great care that their sutures do not impinge on the crest of the muscular ventricular septum.

On the superior side, the superior half of the ventricular septal crest is devoid of conduction tissue. The bundle branches take off on their course on the endocardial septal surface, more or less in the middle of the septum. The suture line on the right side, out of necessity crosses the right bundle branch. A right bundle branch block pattern in the pre-operative electrocardiogram, however, is a standard feature in this anomaly. Probably, therefore, no change is apparent on the post-operative tracings indicative of damage to the right bundle branch. The absence of conduction tissues in the superior half of the septum also means that the left ventricular outflow tract and aortic valve are safe areas for surgical manoeuvres, unlike the situation in the normal heart.

Figure 27-64 The cartoon shows the two suture lines that can be used to close the septal defect. In panel A, the line stays on the right side of the ventricular septal crest, crossing only the right bundle branch. The suture line leaves the mouth of the coronary sinus draining into the left atrium and thus goes widely around the atrioventricular node. Superior to the coronary sinus, the suture line follows the leading edge of the atrial septum. Panel B shows how the suture line can stay on the left side of the conduction axis. Care has to be taken to confine suture bites to the fibrous tissue of the bridging leaflets, or a connecting tongue between them, in the region of the crest of the muscular septum, lest there be damage to the left bundle branches. If care is taken to ensure that the sutures avoid the muscular septum, then it is possible to avoid the conduction tissues, but this is probably more dangerous than using the option shown in panel A.

The suture line to be used is again a matter of personal preference. Excellent results have been published using either one of the described strategies. We are of the opinion that it is probably wise to stick with the technique with which one is accustomed, and that produces the desired results.

Atrioventricular block is not the only, albeit the most devastating, result of surgical damage to the conduction tissues. The gravity of condemning patients to life-long artificial pacemaking is a sequel often not sufficiently appreciated. As well as atrioventricular block, other arrhythmias can also be produced by the placement of stitches. In the directly post-operative period, junctional ectopic tachycardias can be life-threatening, calling for core cooling of the patient. Proximity of stitches to conduction tissues, with consequent localised haematoma and oedema, can elicit these tachycardias. Fortunately, with time, these tachycardias tend to extinguish spontaneously, albeit gradually. As far as we are aware, there have been no studies or reports comparing the described two different suture lines with regard to complications of the conduction system.

When a left superior caval vein drains to the coronary sinus, it is impossible to leave the sinus draining into the left atrium. If this were the case, the resulting right-to-left shunt would be sizable, causing cyanosis. When there is a persisting left superior caval vein, however, the margin for safety between the orifice of the coronary sinus and the leading edge of the atrial septum is significantly smaller, thus rendering the conduction tissues more vulnerable.⁷⁷ The likely course for the suture line in these cases is widely around, and to the right, of the excessively wide mouth of the coronary sinus, unless, of course, the line itself has been brought along the left side of the ventricular septum. Sometimes, nonetheless, the superior caval vein drains into the left atrium, is absent or malformed, or else there is malalignment between the atrial and ventricular septums. In the latter situation, as already discussed, the best guide to the location of the node is the point at which the ventricular septum approaches the atrioventricular junction⁷⁸ (see Fig. 27-22).

Repair of the Left Atrioventricular Valve

Two schools of approach had evolved in past decades for repair of the left atrioventricular valve. Some argued that, since the left atrioventricular valve is trifoliate rather than bifoliate, it should be treated as such. The normal mitral valve, of course, has two leaflets, and takes its name from the Episcopal mitre. Thus, those espousing the trifoliate approach argued that the basic arrangement of three leaflets should be respected during surgery. Valvar repair, in these circumstances, was then said to be indicated only in the presence of regurgitation.^{79,80} The alternative view was that a cleft exists in an, albeit abnormal, mitral valve. Those taking this stance argued that closure of the purported cleft was essential, irrespective of absence or presence of regurgitation, to restore the structure of the valve.^{81–85} Protagonists of both schools had been driven to assume polarised stances, whilst it was claimed by each school that acceptable results could be obtained using their approach. As has been shown since our previous edition, good and particularly sobering evidence has emerged that the approach involving closure of the zone of apposition between the bridging leaflets, irrespective of the true nature of the so-called cleft, produces superior long lasting results, particularly concerning the competence of the left atrioventricular valve. It must be admitted, nonetheless, that there is also rare evidence for the contrary, the reasons for which escape us.⁸⁶ A landmark paper, coupled with rich personal experience with reoperations for leaking valves, has convinced us that it is, indeed, mandatory to close the zone of apposition between the bridging leaflets.⁸⁷ The paradox is that, although the zone is not a cleft in an otherwise normal mitral valvar leaflet, it should be closed to prevent future regurgitation. The morphologic reason for this course of events is probably the fact that the zone is often not well supported by cords, leading to later regurgitation should it be left alone.⁸⁸

A uniform technique for suturing the zone of apposition is essential in producing a lasting effect, and calls for four indispensable considerations. First, the zone should be closed from the septal aspect to the leading edge at which

Figure 27-65 The zone of apposition between the left ventricular components of the bridging leaflets should be closed carefully, using interrupted sutures so as to avoid shrinkage of tissue leading to central regurgitation. Braided non-absorbable suture material is advisable to prevent rupture. The zone should be closed at the line of coaptation, which is different from the leading edge.

the major cords are attached. Second, the ridge where the two leaflets coapt should be sutured, not the physical edge of the leaflet, in order to prevent distortion of the leaflets. Third, single sutures should be used so as not to reef inadvertently the suture line, this happening producing central leakage. Fourth, a braided nonabsorbable suture material should be used, since the repetitive forces predispose to rupture (Fig. 27-65).

Post-operative stenosis when the mural leaflet is small or absent has been documented after closure of the zone of apposition. An absent mural leaflet is usually accompanied by a single papillary muscle. Small or absent mural leaflets are usually seen guarding the entrance of small left ventricles, in other words in the setting of right ventricular dominance. Such hypoplastic left valves, being already small for body size, become stenotic when the zone of apposition is sutured completely. This is understandable, because it would be the equivalent of closing half of an otherwise normal mitral valve. The surgical problem posed by these valvar dispositions can then be impossible to solve perfectly. The choice can well be between leaving some stenosis and some regurgitation. The anatomical variability in the sizes of the leaflets can be quantified intra-operatively using a device that measures the angular size of the leaflets, presuming the basic shape of the left atrioventricular valve to be a circle (Fig. 27-66). The size of leaflets, obviously, is a combination of the valvar diameter, the angular size of the leaflets, and the anatomical centre of the valve (see Fig. 27-57). Unusually large, as well as small, mural leaflets can be part of anatomical proportions making for a difficult repair.⁸⁹

If regurgitation is still present when saline is instilled in the left ventricle, the specific site of regurgitation must be defined. If regurgitation is located at either one of the juxta-mural commissures, annuloplasty of that specific section is performed. If regurgitation is located at the zone of apposition

Figure 27-66 The cartoon shows the technique for measurement of the angular size of the valvar leaflets. Extremely small mural leaflets, guarding less than 45 degrees, are usually associated with a single papillary muscle. In these situations, care should be taken not to produce stenosis by closing the zone of apposition between the left ventricular components of the bridging leaflets.

between inferior and superior bridging leaflets, these leaflets are sewn together, starting at the pericardial patch and continuing until regurgitation is abolished. If no regurgitation is present, no further surgery is warranted, and the atrial part of the septal defect is then closed with the patch.

Repair by creating a double orifice is a technique that has merit when no other conventional technique seems to result in competence (Fig. 27-67). This method was first described in a patient with atrioventricular septal defect, remarkably in a patient with a double-orifice left atrioventricular valve.⁹⁰ Thereafter, this method was used in patients with anatomically otherwise normal but regurgitating mitral valves, where it became known as the edge-to-edge repair. Further results of this technique in atrioventricular septal defect have been described,^{91,92} and we have a personal experience of 13 patients. In the short- to medium-term,

Figure 27-67 The cartoon shows the creation of dual orifices within the left atrioventricular valve using a central pledgeted stitch. The apex of the mural leaflet is sutured to the end of the zone of apposition between the left ventricular components of the bridging leaflets. The two orifices should be measured, and their combined area should not be less than Z-2 for body surface area.

the technique seems to work well, its major drawback being the potential for creating stenosis. We hypothesised that the joint surface area of the two orifices should be as large as the area of the orifice of the normal mitral valve for a patient of comparable body surface area but without an atrioventricular septal defect (Fig. 27-68). This hypothesis results in a formula and a nomogram that can be used in the operating theatre so as to avoid stenosis. Long-term results, however, are lacking.

Reoperative surgery for left atrioventricular valvar regurgitation, or rarely stenosis, differs in its possibilities and risks as compared to reoperations on the mitral valve. The possibilities for repair are somewhat larger in that the zone of apposition that is not closed fully can easily be sutured so as to abolish regurgitation. The edges are usually extremely fibrosed, which facilitates closure. Tissue advancement can alleviate central shortage of valvar tissues.⁹³ If repair fails, and the valve has to be replaced, care has to be taken not to create obstruction within the left ventricular outflow tract. It is wise then to resect the inferior wall of the outflow tract with the aid of a dental mirror so as to abolish any possible obstruction, whilst at the same time avoiding damage to the aortic valve.³¹

Surgery for Dual Orifices in the Left Atrioventricular Valve

Dual orifices in the left or right ventricular components of the atrioventricular valve occur in about one-twentieth of patients, more often in the setting of separate left and right valvar orifices.⁹⁴ Although recognition is difficult, such valves with dual orifices can be suspected using pre-operative echocardiography.⁹⁵ It is an abnormal and incomplete connection between two of the leaflets that forms the anatomical basis for the extra orifice, which in

the setting of the left valve is usually committed to a inferomural or superomural papillary muscle and, most significantly, is usually not regurgitant. Should the abnormal connection between leaflets be severed, joining together the two orifices, catastrophic regurgitation is certain to ensue. Consequently, the possibilities for surgical repair of these valves are limited. Any annuloplasty will reduce even further the effective area of the valvar orifice. The need to replace these valves, therefore, is substantially greater than for the usual trifoliate left valve with a single orifice. If possible, these extra orifices are best left alone.

Association with Tetralogy of Fallot

The relative paucity of papers on clinical results describing the repair of the combination of atrioventricular septal defect and tetralogy of Fallot is not in keeping with the reported incidence of this combination, said to be present in about one-twentieth of all patients with atrioventricular septal defect. Papers of substance describe experience in extremely small series, although some larger series have appeared.^{96,97} This paucity of reports might be explained by publication bias, or by selection of patients. Publication bias could play a role when the results are so bad that clinicians feel disinclined to publish. Notably, case reports on failures are singularly absent. Selection of patients could also play a role when operation is deemed unsuitable because of natural palliation, with the pulmonary stenosis counterbalancing the potential shunt in the setting of fairly well functioning atrioventricular valves. Down's syndrome is present in about three-quarters of these patients, which to some clinicians is a further argument against repair. Such patients can be only mildly symptomatic. Previously, the generally accepted policy for treatment was to palliate first

Figure 27-68 The table shows how the diameters of two separate orifices can be converted to the equivalent diameter of a single orifice. When the diameter of one orifice is indicated in the leading column and the diameter of the other orifice in the leading row, their combined orifice area can be found at the intersection of column and row.

with an arteriopulmonary shunt, and undertake surgical repair only after the age of 4 years. Evidence now favours primary repair.

Intraoperative Echocardiography

Intraoperative epicardial or transoesophageal echocardiography has become standard practise in surgical correction of atrioventricular septal defect. Pre-bypass evaluation is sometimes indicated. Obtaining additional information concerning the morphology of the left ventricular part of the atrioventricular valve is most essential. The function of this left atrioventricular valve is further assessed in detail by colour-coded Doppler imaging. An image of the left ventricular outflow tract is also obtained in order positively to exclude obstruction.

The imaging procedure is then repeated at the completion of the operative procedure. Not only can the resulting anatomy be reassessed, but also colour-coded Doppler imaging will visualise residual shunts after correction and, most notably, reveal any valvar regurgitation. The location of regurgitation, or of a residual shunt, can then be visualised, indicating the possible need for further repair and facilitating its execution. Residual interventricular shunting should not be accepted, because such shunting is unlikely to disappear spontaneously. When significant, it may lead to post-operative annular dilatation and progressive left atrioventricular valvar regurgitation. Quantification of residual regurgitation, however, is notoriously difficult and disappointing, since its degree often seems to increase in the days immediately after operation. Epicardial echocardiography is more versatile, and usually permits the recording of images of better quality in small infants. A potential problem is that use of expanded polytetrafluoroethylene for the patch creates echo dropout, blinding the area behind the patch to echocardiographic interrogation. It is in this precise position, unfortunately, that the usual planes of epicardial imaging reveal the left atrioventricular valve. Although use of tanned autologous pericardium for the patch gives fewer problems during epicardial imaging, transoesophageal echocardiography is generally recommended for larger infants and children.

Post-operative Management

After the operation, the patient is kept intubated and ventilated until the haemodynamic situation is stable. Because of the known tendency of these post-operative patients to develop pulmonary hypertensive crises, it is wise to prevent acidosis, and to avoid other precipitating factors, such as overly vigorous intratracheal suction. Monitoring of pulmonary arterial pressure is advantageous in patients known to have pulmonary hypertension. Ventilation with nitric oxide has a tremendously advantageous effect in post-operative care for patients suffering from pulmonary hypertensive crises. It may be necessary to prolong such inhalation of nitric oxide until pulmonary vascular resistance drops.^{84,98,99}

Monitoring of left atrial pressure has now become standard practise after surgical repair. The presence of a conspicuous left atrial v wave, both before and after the procedure, is a good indication for regurgitation. The absence of a v wave, unfortunately, is not a foolproof indicator that the valve will be competent immediately after repair, possibly because of the altered haemodynamics due to anaesthesia, or through the damping effect of a large atrium. Presence of substantial v waves, nonetheless, is an indication

for further investigation and, usually, further attempts at repair of the valve. Even in the absence of problems with repair of the left atrioventricular valve, monitoring of the left atrial pressure facilitates post-operative management, particularly in control of the fluid balance and treatment of pulmonary hypertensive crises. Monitoring of pulmonary arterial pressure, in contrast, is not routinely necessary. It is prudent, nonetheless, to monitor this value when it is known to be strongly elevated, since the evidence obtained facilitates management of pulmonary hypertensive crises with inhalation of nitric oxide or intravenous substances.

Results of Surgical Repair

Categorisation of lesions does demand a special word of caution. It has been a long-standing custom to categorise as intermediate all those patients who do not have either exclusively atrial shunting, or else a significant ventricular shunt in the setting of a common valvar orifice. Usually, these so-called intermediate types are associated with a higher mortality subsequent to operative correction. If such cases are excluded from the overall series then, by default, the results will improve for those in the stereotypic complete and partial categories. Furthermore, many different definitions exist for categorisation of the presumed intermediate variants, thus confounding comparison of results. Another source of serious problems in comparing results reflects the differences in criteria used to select patients for operative repair. These differ markedly among surgeons but are seldom mentioned in surgical reports. It makes a lot of difference, for example, if one either accepts or rejects for surgical repair children with markedly elevated pulmonary hypertension, those with ventricular imbalance, and those with serious atrioventricular valvar deficiencies. Criteria for exclusion, therefore, should be mentioned explicitly when reporting the results of surgical correction, and journal editors should make it their policy to insist on such descriptions. Ideally, any report of surgical correction should also include the results of medical treatment for those children who, for whatever reason, were not submitted to repair. The necessary prerequisite for such an ideal study, namely, a stable community provided with a comprehensive system of health care, is, sadly, not uniformly present. With the information available, it seems currently that the function of the left atrioventricular valve, ventricular imbalance, and pulmonary hypertension are the sole incremental surgical risk factors for death.

Results of surgical repair have improved steadily over the decades, concomitant with developments in medical therapy, more appropriate criteria for selection, and improvements in myocardial preservation, surgical skill, and post-operative care. The difference in mortality when repair of defects with shunting at ventricular level is compared with repair for those with exclusively atrial shunting has largely disappeared. The function of the left atrioventricular valve has determined the operative result, in both the short and the long term. Late reoperations for left atrioventricular valvar dysfunction have been a source of considerable morbidity, and indeed also mortality. It is the results over the long term, obviously, that matter most, but current analysis of such results reflects the techniques and practises used in previous eras. It is not so easy, at the same time, to estimate the long-term efficacy of modern techniques, because good short-term results do not preclude problems over the long term.

The results published to date include the follow-up over a period of 43 years of a surgical correction between 1958 and 2000 of 133 patients with shunting exclusively at atrial level. Actuarial survival was 78%.¹⁰⁰ Operative methods employed during this period reflect contemporaneous knowledge and fashions. Mortality at 30 days was about 7%, which currently could be expected to be no more than 1%. Extrapolating from this premise would make predicted actuarial survival for current patients about 84%. Survival of an age- and era-matched population without any congenital cardiac anomaly was about 90%. Subtraction of these two figures leads us to predict an excess mortality of just 6% 43 years after the surgical correction. Similar results have been reported elsewhere,^{101,102} but it is impossible to predict with total accuracy the outcomes for correction at the present time, albeit that results are anticipated to be excellent for those with shunting exclusively at atrial level, presuming it is possible to create a competent left atrioventricular valve.

Long-term results for repair of those having a common atrioventricular valve are well documented in analysis of 801 children in Sweden born alive between 1973 and 1997.¹⁰³ Mortality at 30 days for the 502 patients undergoing surgical correction over the last 5 years of the study was 1%. The actuarial survival curve flattens off after 1 or 2 years, and shows a loss of lives of about 10% in 30 years. How this compares to an age- and era-matched population is not known. Although similar results have been published, there are not many papers on results over the long term¹⁰⁴ (see Table 27-1).

Down's Syndrome

Discussion of surgical treatment of atrioventricular septal defect cannot be concluded without consideration of the problems created by co-existing Down's syndrome. Three principle issues are at stake. First, it is often claimed that children with Down's syndrome have a higher incidence of pulmonary hypertension. Second, the anatomical spectrum is different in children with Down's syndrome when compared with their chromosomally normal peers. Third, there has been some controversy on the perceived benefit of surgical repair. Pulmonary hypertension is about 10 times more prevalent in patients with Down's syndrome, and has an earlier onset.¹⁰⁵ Those patients with Down's syndrome, therefore, must undergo surgery at a very young age, preferably before 6 months,¹⁰⁶ while some argue for even earlier repair.¹⁰⁷ Pulmonary hypertension has been reported to be more prevalent in those having the Rastelli A configuration.¹⁰⁸

Obstruction to left ventricular inflow and outflow, in contrast, is said to be far less frequent in the setting of Down's syndrome.¹⁰⁹ This probably reflects the more frequent existence of common valvar orifice in association with trisomy 21. Extensive bridging of both inferior and superior leaflets, rather than one or both leaflets being committed primarily to the left ventricle, is more usual in children with trisomy 21. Accordingly, the angle of the zone of apposition between the inferior and superior leaflets is usually perpendicular to the ventricular septum in children with Down's syndrome, while this angle is often crooked, and deviated from perpendicular, in those with normal chromosomes. Recently published series show that Down's syndrome is not a risk factor for surgical repair. If anything, anatomy is more favourable in those with trisomy 21. It is pulmonary vascular resistance, itself related to age, and other associated problems, that determine the risk for these patients.¹¹⁰

ANNOTATED REFERENCES

- Becker AE, Anderson RH: Atrioventricular septal defects: What's in a name? J Thorac Cardiovasc Surg 1982;83:461-469.

In this important review, it was the common morphologic features that were promoted as the best denominator for naming these defects so as also to understand the anatomy. Older names implying presumed developmental mechanisms, such as atrioventricular canal and endocardial cushion defect were rejected as being non-descriptive and embryologically speculative.

- Ebels T, Anderson RH, Devine WA, et al: Anomalies of the left atrioventricular valve and related ventricular septal morphology in atrioventricular septal defects. J Thorac Cardiovasc Surg 1990;99:299-307.

This review of the large series of specimens in the Pittsburgh archive permitted documentation of the anatomical variability in sizes and presence of left valvar leaflets, these then being put into a logical sequence. This variability was related to left ventricular size, to the morphology of the ventricular septum, and to the size of the atrioventricular septal defect.

- Thiene G, Wenink ACG, Frescura C, et al: Surgical anatomy and pathology of the conduction tissues in atrioventricular septal defects. J Thorac Cardiovasc Surg 1981;82:928-937.

The anatomy of the conduction system in atrioventricular septal defect was reviewed, and put into context of previous studies, providing the anatomical basis for its avoidance during surgery.

- Anderson RH, Ho SY, Becker AE: Anatomy of the human atrioventricular junctions revisited. Anat Rec 2000;260:81-91.

The atrioventricular junction being common to both ventricles is essential in understanding atrioventricular septal defect. In this paper, the authors review the structure of the normal atrioventricular junctions. The state of the junctions is unrelated to the presence of a septal defect permitting a shunt. This concept increases our understanding the paradox of atrioventricular septal defect with intact septal structures.

- Kaski JP, Wolfenden J, Josen M, et al: Can atrioventricular septal defect exist with intact septal structures? Heart 2006;92:832-835.

After isolated reports of hearts displaying all features of atrioventricular septal defect with paradoxically intact septal structures, this was the first paper to address this phenomenon from the clinical stance. Many more of these patients must exist, albeit being unrecognised as such, possibly displaying only some degree of left valvar regurgitation. Some of these patients may also have hearts without any functional defect.

- Wetter J, Sinzobahamvya N, Blaszczyk C, et al: Closure of the zone of apposition at correction of complete atrioventricular septal defect improves outcome. Eur J Cardiothorac Surg 2000;17:146-153.

Closure of the zone of apposition during surgical correction of atrioventricular septal defect had been contentious for nearly two decades. Those choosing not to close the zone argued that the trifoliate nature of the valve had to be maintained. The results of this important study showed that non-closure resulted in a substantial proportion of patients needing reoperation for secondary closure of the leaking valve. The paradox is that, while the zone of apposition cannot be compared to a cleft in an otherwise normal leaflet, it must still be closed.

- Mahle WT, Shirali GD, Anderson RH: Echo-morphological correlates in patients with atrioventricular septal defect and common atrioventricular junction. Cardiol Young 2006;16(Suppl 3):43-51.

The paper describes well how the anatomy of atrioventricular septal defect can be visualised by various echocardiographic planes, emphasizing their limitations. It also introduces the potential value of three-dimensional echocardiography.

- Najm HK, Van Arsdell GS, Watzka S, et al: Primary repair is superior to initial palliation in children with atrioventricular septal defect and tetralogy of Fallot. J Thorac Cardiovasc Surg 1998;116:905-913.

The group from Toronto presents an analysis of the largest series of patients with the combination of atrioventricular septal defect and tetralogy of Fallot. Their evidence shows that primary repair is the preferred surgical option.

- Frid C, Björkhem G, Jonzon A, et al: Long-term survival in children with atrioventricular septal defect and common atrioventricular orifice in Sweden. Cardiol Young 2004;14:24-31.

With a maximum follow-up of 28 years, this is the longest comprehensive follow-up of a series of patients undergoing surgery for all forms of atrioventricular septal defect. The 20-year survival of 61% obviously reflects older surgical and medical techniques, but the decreasing slope of the survival curve is a comforting observation.

- Kogon BE, Butler H, McConnell M, et al: What is the optimal time to repair atrioventricular septal defect and common atrioventricular valvar orifice? Cardiol Young 2007;17:356-359.

The issue of timing of operation for atrioventricular septal defect with unrestricted ventricular shunt is addressed well in this paper. The authors convincingly demonstrate that operation before the age of 6 months is now possible with low mortality, albeit at the cost of higher morbidity and a higher incidence of complications.

Ventricular Septal Defects

LEE N. BENSON, SHI-JOON YOO, FAHAD AL HABSHAN, and ROBERT H. ANDERSON

Holes between the ventricles can occur as isolated anomalies, but are also seen in association with many other defects. For example, they are found as integral parts of entities such as the tetralogy of Fallot, double-outlet ventricles, and most cases of common arterial trunk. They occur as a component of atrioventricular septal defects with common atrioventricular junction, and are frequently encountered in association with transposition and congenitally corrected transposition. They are an integral part of the functionally univentricular circulation. Taken together, they unequivocally make up the commonest congenital cardiac malformation. In this chapter, we consider only the so-called isolated examples, albeit that we discuss the complications produced by other minor associations. Although holes between the ventricles have a long pedigree, it is with the name of Henri Roger¹ that the anomaly is historically linked. It was Roger who recognised that an isolated ventricular septal defect produced a typical murmur, and could be consistent with prolonged life and good health.

PREVALENCE

If we exclude aortic valves having two leaflets, and also exclude prolapse of the mitral valve,² then isolated ventricular septal defect is the most common congenital cardiac malformation. It is difficult to obtain an accurate assessment of prevalence, since most individuals with an isolated defect, being asymptomatic, are not candidates for cardiac catheterisation and angiography. In the past, therefore, there frequently was no objective proof of the presence of a defect. It was the advent of cross sectional echocardiography, and colour flow Doppler, that changed all that. The known high rate of spontaneous closure³ meant that postmortem data certainly underestimated the incidence of the defect. In series depending heavily on clinical observation, the estimated prevalence has varied markedly. The incidence has been shown to be higher in fetuses dying prenatally, and there is some variation depending on the time of fetal death. Hoffman⁴ summarised the literature addressing the proportional distribution of congenital cardiac defects from 22 series, showing that the median distribution for ventricular septal defect was 31%. The most accurate clinical data comes from the prospective Bohemia survival study,⁵ which revealed a prevalence of 2.56 per 1000 live births, accounting for two-fifths of all cardiac malformations, similar to the data from Merseyside in the United Kingdom, where the figure was 2.74 per 1000 births.⁶ A study from Malta, in contrast, revealed a figure of 3.94, a significant difference.⁷ This reflects the increased use of echocardiography in diagnosis. This trend

is confirmed by data from the Baltimore–Washington Infant Study,⁸ which also used echocardiographic techniques, and showed a remarkable increase in the diagnosis of muscular defects, with a tenfold increase in prevalence. Ventricular septal defects accounted for one-third of the lesions identified in the infants of this study, and made up over two-fifths of the malformations encountered in Malta. A particularly high prevalence of muscular defects has also been reported by those who scanned populations of neonates using colour flow imaging, noting subsequent spontaneous closure of many of the defects.^{9–12} None of these studies, however, were population based.¹³ Ventricular septal defects are more common in premature infants, and those born with low weight. Incidence, however, is not related significantly to race, sex, maternal age, birth order, or socioeconomic state.

While there does not appear to be a genetic bias towards the incidence of ventricular septal defects, genetics do influence the specific type of defect. The doubly committed subarterial, or juxta-arterial, defect is more common in Asian populations, whereas muscular and multiple defects are less common in the same population. According to Wilkinson,¹⁴ the frequency of the doubly-committed subarterial or juxta-arterial defect requiring repair accounts for at least 30% in an Asian population, compared with the incidence of about 5% of Occidental patients requiring surgery in Western societies. Wilkinson¹⁴ also noted that, while muscular defects account for about three-tenths of defects requiring closure in the Western world, they are uncommon in the Asian population referred for surgical closure, where multiple ventricular septal defects are very rare. Such multiple muscular defects account for one-tenth of operative closures in the west.

MORPHOLOGY AND MORPHOGENESIS

Categorisation of Defects

It is, perhaps, surprising that, as we start the 21st century, there is still no consensus concerning the best way to categorise and describe holes between the ventricles. The lesion, however, is not always as simple as it first appears. For example, when the hole between the ventricles is overridden by an arterial valve, it is open to debate as to which plane in space represents the defect.¹⁵ This is because the septum that interposes between the outflow tracts is no longer an interventricular structure. This fact, in itself, negates the possibility of defining a ventricular septal defect as a simple hole in the substance of the ventricular septum. This situation is magnified in the setting of double-outlet right ventricle. In this setting, the hole in

TABLE 28-1

CRITERIONS FOR CLASSIFICATION OF A VENTRICULAR SEPTAL DEFECT

Define the plane of the defect
Define the boundaries of the defect
Account for the anatomical features:
The relation of the defect to the atrioventricular conduction axis
The relation of the defect to the atrioventricular valves
The relation of the defect to the arterial valves
The position of the defect within the ventricular septum: opening to the inlet, apical trabecular, or outlet parts of the right ventricle
The size of the defect

the ventricular septum, or the interventricular communication, functions as the outlet from the left ventricle. Surgical correction of patients with double outlet right ventricle, therefore, is based on the concept of tunneling this hole to one or other of the ventricular outflow tracts. In this setting, closure of the hole between the ventricles would wall off the left ventricle from both arterial trunks. Because of these subtle differences in the potential definition of septal defects, different investigators have chosen different features on which to base their criterions for classification. It is hardly surprising, therefore, that currently there is lack of consensus on the best options for categorisation. Indeed, as yet there is no agreement on what defines a ventricular septal defect. Our proposal for definition and classification is based upon several principles (Table 28-1).

First, it is necessary to define clearly and unambiguously the plane of space chosen to represent the defect. Having defined this plane, the second principle is to account for all its various anatomical features. Most important of these are its boundaries. As we will show, it is the structure of the boundaries that permits phenotypic categorisation. Having established the phenotype of the defect, it is then necessary to describe the position of the hole relative to the landmarks and components of the ventricular septum, including the surgically significant atrioventricular conduction axis. If present, it is also necessary to take account of valvar overriding. When either an atrioventricular or an arterial valve overrides the crest of the muscular ventricular septum, then of necessity there is malalignment between the different septal components. Attention must also be given to the size of the hole chosen to represent the defect. The system, to be used throughout our volume, and forming the basis for the categorisation used in the European Paediatric Cardiac Code,¹⁶ caters for all these features. As we will subsequently show, this system is applicable not only to isolated defects to be described in this chapter, but for those in all the various settings described elsewhere in these pages.

What Is the Defect?

When there is a simple hole, punched as it were into the substance of the muscular ventricular septum, then there is no problem in defining its margins, nor in agreeing that the margins are exclusively muscular (Fig. 28-1). Many holes, however, have the crest of the muscular ventricular septum as one of their margins, but abut directly upon the hinge-points

Figure 28-1 The hole in this heart (bracket) is enclosed within the muscular septum. None would have difficulty in establishing the margins of the defect, and recognising that it opens between the ventricular inlets.

of the leaflets of either the atrioventricular or the arterial valves (Fig. 28-2), or on occasion the attachments of both the arterial and atrioventricular valvar leaflets. Some of these lesions are associated with marked overriding of an arterial or atrioventricular valvar orifice. An example of overriding of the arterial valve is demonstrated in Figure 28-3. In this particular circumstance, it is much harder to define the precise borders and margins of hole between the ventricles. This is because an inverted cone of space, with an elongated base, extends from the attachments of the leaflets of the overriding arterial valve to the crest of the muscular ventricular septum (Fig. 28-4). Within this inverted cone, any of a number of planes can justifiably be nominated to represent the defect. When viewed in a single section, as seen by the echocardiographer, then at least three of these planes are important (see Fig. 28-4). One is the continuation of the long axis of the ventricular septum to the underside of the overriding valvar leaflets, the green oval as shown in Figure 28-4. This particular choice for defining the defect, which without question represents the plane of the superior continuation of the muscular ventricular septum, exists only when the valvar leaflets are closed. Even though this plane represents the geometric interventricular communication, it is never the locus for placement of a patch by the surgeon during operative repair of an isolated defect. Indeed, when the arterial valvar leaflets open during ventricular systole, the superior margin of this hole is the underside of the aortic arch! The second plane, shown by the yellow oval in Figure 28-4, marks the boundary between the cone of space subtended beneath the overriding valve and the left ventricle. This plane is the opening from the left ventricle to the subaortic outflow tract, presuming that it is the aortic valve which is

Figure 28-2 It is much more difficult to identify the precise plane of the defect (*open arrow*) in this heart, sectioned to replicate the parasternal long-axis oblique plane incorporating the aortic root. The aorta is overriding the crest of the ventricular septum, and the superior margin of the defect is formed by fibrous continuity between the leaflets of the aortic and tricuspid valves (see Fig. 28-3).

overriding the septal crest. Although unequivocally important, this plane is also unlikely to be chosen as the septal defect. The third plane, shown as the red oval in Figure 28-4, has features in common with the second, in that it marks a ventricular border of the inverted cone of space. This plane, to our eyes, is of greatest practical importance, since it is the border around which the surgeon will insert sutures to secure a patch placed to prevent shunting between the ventricles. It is also the position where the interventionist will place a device with the same goal in mind. It is this third plane, therefore, that we choose to define as the ventricular septal defect, considering the hole as the plane of space that must be closed so as to restore septal integrity. It is the difference in the anatomical make-up of the margins of this hole, as viewed from the morphologically right ventricle, which provide the phenotypic features of the different types of defect. This also is the view obtained by the surgeon when restoring septal integrity in the operating room. In many instances, the hole closed by the surgeon to restore septal integrity is also the obvious hole within the ventricular septum (Fig. 28-5). In these situations, therefore, the septal defect and the interventricular communication are one and the same. In the situation of double outlet right ventricle, this is obviously not the case (Fig. 28-6). When both arterial trunks arise from the right ventricle, the hole closed so as to restore septal integrity is the plane from the crest of the muscular ventricular septum to the underside of the right ventricular outlet septum. This hole is now markedly different from the interventricular communication, which is the outlet for the left ventricle. In the setting of double outlet right ventricle, therefore, as already discussed, it would be a disaster if the

Figure 28-3 In this example (A), with its equivalent echocardiogram (B), the degree of aortic valvar overriding is more obvious. There is now an inverted cone of space that extends from the attachments of the valvar leaflets (*bracket*) to the crest of the ventricular septum (*star*). It is reasonable to nominate any plane within this cone as a ventricular septal defect, but three particular planes are of special importance (see Fig. 28-4).

Figure 28-4 Within the cone as illustrated in Figure 28-3, at least three planes are particularly important. They are the right ventricular margin (red oval), the plane of the interventricular communication marked by the upward continuation of the ventricular septum (green oval), and the left ventricular margin (yellow oval). When categorising the hole between the ventricles, we use the features of the right ventricular margin, this being the space closed by the surgeon to restore septal integrity.

surgeon chose to close the interventricular communication, as opposed to the hole which, when closed, restores septal integrity (see Fig. 28-6).

Features Requiring Description

As shown, the holes to be closed so as to restore septal integrity are either found within the muscular septum, or else at its margins. The holes at the margins of the muscular

septum can be related directly to the hinges of the leaflets of the atrioventricular, or those of the arterial valves, or in some circumstances to the leaflets of both arterial and atrioventricular valves. It is an appreciation of these relationships, as viewed from the right ventricle, which we use as the primary criterion for description. When considered from this stance, all defects can be placed into one of four groups, namely those which are muscular, those which are perimembranous, those which are juxtatricuspid (and non-perimembranous), and those which are both doubly committed and juxta-arterial (Fig. 28-7 and Table 28-2).

Muscular Defects

Those holes within the substance of the septum of necessity have exclusively muscular rims, and hence are described as muscular defects (Fig. 28-8).

Perimembranous Defects

The second group of holes are those related to the aortic root, opening into the right ventricle in the area where the subpulmonary outflow tract turns superiorly relative to the atrioventricular junction. We describe this area as the inner curvature of the right side of the heart (Fig. 28-9). When the ventricular septum is intact, this is the area occupied by the membranous part of the septum, with the supraventricular crest separating the area from the leaflets of the pulmonary valve (see Chapter 2). The membranous septum, on its left ventricular aspect, is directly continuous with the area of fibrous continuity between the leaflets of the aortic and mitral valves. The right end of this zone of continuity is called the right fibrous trigone. It is fusion of this trigone with the membranous septum that produces the central fibrous body (Figs. 28-10 and 28-11).

This entire area is then part of the fibrous root of the aorta, and is itself continuous with the triangle of fibrous tissue which ascends to occupy the space between the non-coronary and right coronary leaflets of the aortic valve. On the right side, the membranous septum itself is

Figure 28-5 The cartoon (A), along with an equivalent echocardiogram (B), shows the arrangement in which there is a simple hole within the muscular ventricular septum (double-headed arrow). This is the interventricular communication, and is located between the crest of the muscular ventricular septum (star) and the underside of the muscular outlet septum (green oval). This is the hole closed so as to restore septal integrity. In this situation, there is no problem in defining the interventricular communication as being the ventricular septal defect.

Figure 28-6 The cartoon (A), together with an equivalent echocardiogram (B), shows the arrangement in which both arterial trunks arise in their entirety from the morphologically right ventricle. The muscular outlet septum (*green oval*) is now a right ventricular rather than an interventricular structure. The plane closed so as to restore septal integrity (*red dotted line*) is now within the cavity of the right ventricle. It is no longer the interventricular communication (*double-headed arrow*). Indeed, in this situation it would be a disaster to close the interventricular communication. The ventricular septal defect, therefore, or the red dotted line, is no longer the same thing as the interventricular communication. The *star* shows the crest of the muscular ventricular septum. LV, left ventricle; PT, pulmonary trunk.

Figure 28-7 The cartoon shows the locations of the various phenotypic types of holes permitting shunting between the ventricles as seen from the right ventricle.

crossed by the hinge of the septal leaflet of the tricuspid valve, dividing it into atrioventricular and interventricular components. The axis of atrioventricular conduction tissue penetrates through this septum from the apex of the triangle of Koch (see Chapter 2). Having penetrated, when

TABLE 28-2

CLASSIFICATION OF THE BORDERS OF VENTRICULAR SEPTAL DEFECTS

Defects abutting on area of continuity between atrioventricular and arterial valves (perimembranous)
Opening into inlet of right ventricle
Opening into outlet of right ventricle
Confluent defects
Defects encased within musculature of ventricular septum (muscular)
Opening to the inlet of the right ventricle
Opening between the apical components
Opening to the subpulmonary outlet
Multiple
Co-existing with perimembranous defect
Defects roofed by arterial valves in fibrous continuity (doubly committed and juxta-arterial)
With muscular postero-inferior rim
Extending to become perimembranous
Defects roofed by the tricuspid valve, with an intact membranous septum

Figure 28-8 Holes with exclusively muscular borders, as seen from the right side, can permit shunting to the inlet, to the apical component, or to the outlet of the right ventricle. Depending on their location, they will bear different relationships to the atrioventricular conduction axis, shown in red. The membranous septum, perforated by the conduction axis, is shown in yellow.

Figure 28-9 When a hole between the ventricles is at the borders of the muscular septum, and opens into the right ventricle in the area between the membranous septum and the subpulmonary infundibulum, the area we call the inner curvature (*cross-hatched area*), it is formed postero-inferiorly by fibrous continuity between the leaflets of the superiorly located aortic and posteriorly located tricuspid valves (see also Fig. 28-10). The membranous septum is then an integral part of this fibrous continuity, albeit usually shielded from view by the septal leaflet of the tricuspid valve. The conduction axis, as it penetrates from atrium to ventricle, is directly related to this postero-inferior border (see Fig. 28-15). We describe any defect possessing this phenotypic feature as perimembranous.

the septum is intact, the conduction bundle runs on the crest of the muscular septum, being sandwiched between the fibrous and muscular septal components, along the postero-inferior margin of the interventricular part of the membranous septum. When the ventricular septum is deficient in this area, it springs apart between these two septal components. In consequence, the postero-inferior margin of the defects opening from the aortic root is formed by fibrous continuity between the leaflets of the aortic and tricuspid valves (see Fig. 28-9). In the past, such defects were often called membranous defects, since it

Figure 28-10 The aortic outflow tract of the normal heart is shown having removed the leaflets of the aortic valve. Note that the membranous septum (outlined by blue cross-hatching) is continuous with the right fibrous trigone (red cross-hatching) and the interleaflet triangle between the right coronary and non-coronary sinuses of the aortic valve (blue vertical hatching). When the septum comes apart, as it does in the setting of perimembranous defects, it does so between the crest of the muscular ventricular septum and the components of the membranous septum. The interventricular (IV) component of the membranous septum often persists as a flap in the postero-inferior margin of the defect. AV, atrioventricular.

Figure 28-11 This specimen is photographed from the left side, showing that the posterior margin of a defect we categorise as being perimembranous is formed by fibrous continuity between the leaflets of the mitral, aortic, and tricuspid valves. Note the small remnant of the interventricular component of the membranous septum, which is part of the central fibrous body.

was presumed that they existed because of a deficiency in the membranous septum. It was pointed out long since¹⁷ that this is unlikely, since the defects are always larger than the normal dimensions of the membranous septum. Furthermore, the membranous septum is not divided into its interventricular and atrioventricular components until after the embryonic septum has closed.¹⁸ It seems far more likely that the defects persist because the muscular ventricular septum is deficient in the environs of the developing membranous septum. Taking account of this fact, we suggested that the defects should be considered

perimembranous.¹⁹ Their anatomical hallmark in the otherwise normally constituted heart is the presence, as seen from the right side, of fibrous continuity between the leaflets of the aortic and tricuspid valves (see Fig. 28-9). When viewed from the left side, the continuity is seen to include also the aortic leaflet of the mitral valve (see Fig. 28-11). Some of these defects, because of associated anomalies of tricuspid valve, such as clefts or perforations of the septal leaflet, or deformity or adherence of valvar tissue to the margins of the septal defect and widening of the antero-septal commissure,²⁰ produce the potential for ventriculo-atrial shunting. Defects of this type are the commonest examples of so-called Gerbode defects.²¹ Ventriculo-atrial shunting can also be produced when there is deficiency of the atrioventricular component of the membranous septum, producing a true atrioventricular septal defect with separate right and left atrioventricular junctions, but these lesions are exceedingly rare (see Chapter 27). They form the rarer variant of the Gerbode defect.²¹

Doubly Committed and Juxta-arterial Defects

There is then a third group of defects that is discrete from the first two groups. The feature of these defects is that they occupy the region in the normal heart formed by the free-standing component of the muscular subpulmonary infundibulum. The infundibulum is the sleeve of free-standing muscle that lifts the leaflets of the pulmonary valve away from the base of the heart. In our initial description,¹⁹ we interpreted this part of the infundibulum as being formed by the muscular outlet septum. We now know this to be incorrect, since as emphasised above, the leaflets of the pulmonary valve, in the normal heart, are supported by a complete sleeve of free-standing infundibular musculature. Defects of this third type, therefore, which are both doubly committed and juxta-arterial, and characterised by fibrous continuity in their roof between the leaflets of the aortic and pulmonary valves (Fig. 28-12), cannot exist in hearts in which the free-standing muscular subpulmonary infundibulum has developed in normal fashion. In other words, the presence of this type of defect implies abnormal formation of the subpulmonary infundibulum in such a way as to permit a hole to exist directly beneath the arterial roots. When viewed from the right ventricle, most defects of this type are seen to have a muscular postero-inferior rim separating the leaflets of the aortic and tricuspid valves. They are, therefore, described as doubly committed and juxta-arterial (see Fig. 28-12, upper panel). On occasion, nonetheless, they can extend so that the postero-inferior margin is formed by fibrous continuity between the aortic and tricuspid valvar leaflets, the roof continuing to be made up of aortic to pulmonary valvar continuity. Defects with such margins are both doubly committed and juxta-arterial and, at the same time, perimembranous (see Fig. 28-12, lower panel).

Juxta-tricuspid and Non-perimembranous Defects

The juxta-tricuspid, and non-perimembranous, defect is very rare. The hole between the ventricles is roofed by fibrous continuity between the leaflets of the tricuspid and mitral valves, but is separated from the area of the membranous septum.²² The atrioventricular valvar leaflets are then in direct contact through the posterior margin of the defect. In contrast to perimembranous defects, the tricuspid valve is not in direct contact with the aortic valve. It was defined on the basis of the four-chamber

Figure 28-12 There is a third phenotypic variant for holes between the ventricles, which we describe as being doubly committed and juxta-arterial. As shown in the cartoon, holes fulfilling the criterion for inclusion in this group are characterised by fibrous continuity between the leaflets of the aortic and pulmonary valves. A, most hearts of this type have a muscular postero-inferior rim that protects the conduction axis (red). This arrangement makes the defect as shown in the upper panel both doubly committed and juxta-arterial, but not perimembranous. B, On the other hand, these defects can also extend so that there is continuity also with the leaflets of the tricuspid valve. The defects are then both doubly committed and juxta-arterial, and perimembranous.

echocardiographic cut, and its angiographic equivalent.²² Those describing the defect commented that it may be difficult to distinguish from a perimembranous defect, and indeed, one of us (RHA) has never encountered an autopsied specimen with such a defect. The conduction axis will be located at the anterior aspect of the defect, coursing along the postero-inferior margin of the intact membranous septum.

Position of Defects

Having accounted for the margins of the various defects, as viewed from the right side, and having used this as our primary criterion for definition, we then describe the position of the defect relative to the landmarks and components of the right ventricle. For the muscular defects, this creates no problems, since these holes are punched within the substance of the muscular septum so as to open directly to the inlet, the outlet, or the apical parts of the right ventricle.

For the perimembranous defects, the situation is more complicated.

Relation of Perimembranous Defects to Components of the Right Ventricle

In our initial account,¹⁹ we described perimembranous defects as excavating into the inlet, outlet, or apical trabecular components of the septum. This is incorrect. Although much of the septum, when viewed from the right side, seems to be positioned to separate the inlet of the right from the inlet of the left ventricle, this is not the case. Because of the deeply wedged location of the normal subaortic outflow tract, the majority of the septum as viewed from the right side in relation to the septal leaflet of the tricuspid valve separates the inlet of the right from the outlet of the left ventricle. As discussed, it is also the case that, in the normal heart, the seemingly septal surface of the right ventricular outflow tract is formed by the free-standing muscular subpulmonary infundibulum. The posterior wall of this muscular subpulmonary infundibulum separates the cavity of the right ventricle from the aortic root, rather than forming a septum between the cavities of the right and left ventricles. Indeed, in the normal heart it is not possible to recognise the boundaries of a discrete muscular outlet septum (see Chapter 2). When perimembranous defects open anteriorly towards the pulmonary valve, they do not excavate directly into the free-standing muscular subpulmonary infundibulum. Instead, the presence of the defect now makes it possible to recognise a discrete muscular outlet septum, which forms the superior margin of the hole between the ventricles. This true outlet septum, located within the right ventricle, can be extensively malaligned relative to the remainder of the muscular septum. The

arrangement permits shunting between the subaortic and subpulmonary outlets (Fig. 28-13). Because of the close relationship of the aortic valve to the tricuspid valve, some of the shunting will still be directed towards the inlet of the right ventricle. Large perimembranous defects, therefore, can be considered confluent, shunting to all parts of the right ventricle.

Valvar Overriding and Septal Malalignment

The third important feature that requires description, when present, is valvar overriding, along with its associated feature of malalignment of septal components. Malalignment can involve the muscular outlet septum, as discussed above. In the situation illustrated thus far (see Fig. 28-13), the outlet septum is a right ventricular structure, as is also the case in tetralogy of Fallot (see Chapter 36). The outlet septum can be deviated posteriorly to become a left ventricular structure, then obstructing the outflow tract of the left ventricle (Fig. 28-14). There can also be malalignment between the muscular ventricular septum and the atrial septum. This is the phenotypic feature of hearts with overriding of the orifice of the tricuspid valve and straddling of its tendinous cords (Fig. 28-15).

Size and Shape of the Defect

Size is obviously important in determining the haemodynamic consequences of the various types of defects, and also in determining those defects most likely to diminish in size or close spontaneously. Size can be described according to taste, either using subjective adjectives such as large, medium or small, or by relating the different dimensions of the plane of space measured as the defect to the diameter

Figure 28-13 These perimembranous defects, shown in the specimen (A) and the subcostal short-axis echocardiogram (B), open into the outlet of the right ventricle. In the specimen, a significant proportion of the aortic leaflets attached to right ventricular, rather than left ventricular, structure. When viewed along the long axis of the ventricular septum, the aortic valvar orifice overrides the crest of the ventricular septum (see also Fig. 28-20). The muscular outlet septum can now be recognised as a discrete structure, located exclusively in the right ventricle, separating the subaortic and subpulmonary outflow tracts, and supporting the free-standing muscular subpulmonary infundibulum. The double-headed red arrow on echocardiogram indicates the defect through which the aortic and tricuspid valves are in direct contact.

Figure 28-14 This specimen (A), and corresponding magnetic resonance image sectioned in parasternal long axis plane (B), show how the muscular outlet septum is deviated posteriorly to obstruct the subaortic outlet.

Figure 28-15 A, In this heart, even though the hole between the ventricles is perimembranous, there is malalignment between the atrial septum and the crest of the muscular ventricular septum, the inferior part of the muscular ventricular septum being deviated anteriorly and superiorly into the right ventricle. This permits straddling and overriding of the tricuspid valve. B, A corresponding subcostal echocardiogram shows malalignment between the atrial and ventricular septum. The tension apparatus of the tricuspid valve inserts to the papillary muscle in the left ventricle through the defect above the crest of the malaligned ventricular septum (star).

Figure 28-16 When viewed in the subcostal long-axis oblique cut of the left ventricular outflow (A), it can be seen that the postero-inferior margin of the perimembranous defect is formed by fibrous continuity between the leaflets of the aortic and tricuspid valves. Note the remnant of the membranous septum in the specimen, forming a membranous flap, which reinforces an area of fibrous continuity between the tricuspid and mitral valves. Panel B shows a comparable echocardiographic section.

of the aortic root. The shape of the defect may also vary; muscular defects are typically round or oval when seen from the right ventricle, although they can be crescentic or cashew-like. Defects that are bordered by atrioventricular or arterial valves are typically half-moon shaped. The shape of the defect may appear different when it is encroached upon by prolapsing leaflets of the aortic valve. When it is not round, the defect may appear larger on one plane than on another as seen using cross sectional and angiographic imaging.

Having discussed the general principles of categorisation, and the system by which we describe ventricular septal defects, we will now consider each of four morphological types of defects in more detail, emphasising their relationships to the atrioventricular conduction axis.

Perimembranous Ventricular Septal Defects

Perimembranous defects are those opening in the region of the inner curvature of the right ventricle, having as their diagnostic feature continuity between the leaflets of the tricuspid and aortic valves, this continuity incorporating also the central fibrous body. In this situation, the crucial postero-inferior part of the margin of the defect as seen from the right ventricle is formed by the area of fibrous continuity (Fig. 28-16). When such defects open to the inlet of the right ventricle, and are viewed from their right side, the crucial distinguishing part is often curtained from view by the leaflets of the tricuspid valve (Fig. 28-17). On occasion, a defect opening between the ventricular inlets can be part of a heart having a common atrioventricular junction (Figs. 28-18 and 28-19). In this setting, the left atrioventricular valve will have three leaflets, and the heart

Figure 28-17 When viewed from the right side, the postero-inferior margin of this perimembranous defect, which opens to the inlet of the right ventricle, is obscured by the septal leaflet of the tricuspid valve. It is still possible to recognise, nonetheless, the landmarks to the location of the atrioventricular conduction axis, these being the apex of the triangle of Koch and the medial papillary muscle.

will show all the other features of an atrioventricular septal defect with common atrioventricular junction (see Chapter 27), albeit with shunting occurring only at the ventricular level because the bridging leaflets of the valve guarding the common junction are firmly attached to the under surface

Figure 28-18 This defect also opens between the ventricular inlets, but on closer inspection it can be seen that the leaflets of the atrioventricular valve bridge through the ventricular septum. The phenotypic feature of this heart is the presence of a common atrioventricular junction, so that the defect is not simply a perimembranous defect opening to the inlet of the right ventricle, as shown in Figure 28-17.

Figure 28-19 The cartoon shows how, in the defect shown in Figure 28-18, the leaflets of the right atrioventricular (AV) valve bridge into the left ventricle, since there is a common atrioventricular junction, but with only shunting at ventricular level through the atrioventricular septal defect (AVSD) because the bridging leaflets are firmly attached to the underside of the atrial septum. Note that the left component of the valve, shown in dotted lines as seen through the intact atrial septum, is trifoliate.

of the atrial septum. Such defects should be distinguished from perimembranous ones opening to the inlet of the right ventricle. Irrespective of their size, the latter defects have separate atrioventricular junctions, with a mitral valve guarding the left junction, even when it is cleft.²³ The hearts already discussed with atrioventricular septal malalignment, and with the tricuspid valve straddling and overriding a defect between the ventricular inlets (see Fig. 28-15),

Figure 28-20 When there is malalignment between the atrial septum and the muscular ventricular septum, seen in the setting of straddling tricuspid valve, then it is no longer possible for the conduction axis, carried on the crest of the ventricular septum, to take origin of the regular atrioventricular node positioned at the apex of the triangle of Koch. Instead, the bundle takes origin from an anomalous node formed at the point where the malaligned ventricular septum meets the right atrioventricular junction.

should also be distinguished from hearts with atrioventricular septal defect and common atrioventricular junction. The ones with overriding of the tricuspid valve constitute a particular subset of perimembranous defect, since they still possess the phenotypic feature of aortic–tricuspid valvar fibrous continuity. The septal malalignment, however, predicates that there will be an anomalous location of the atrioventricular conduction axis (Fig. 28-20). Similar septal malalignment can also be found in the setting of a common atrioventricular junction (see Chapter 27). When perimembranous defects permit shunting primarily to the inlet of the right ventricle, the septal leaflet of the tricuspid valve is frequently divided or deficient. If the two components of the abnormal leaflet are at all bound down to the margins, then shunting can occur from left ventricle to right atrium. Such shunting is frequently held to be caused by absence of the atrioventricular membranous septum, but this is very unusual. Deficiency of the atrioventricular component of the membranous septum can occur, very rarely, in the setting of separate right and left atrioventricular junctions (Fig. 28-21). More usually when there is ventriculo-atrial shunting, this is first across a perimembranous defect, and only subsequently to the right atrium (Fig. 28-22). As already discussed, the two defects permitting ventriculo-atrial shunting are also described as Gerbode defects.²¹

The other frequent type of perimembranous defect is the one that extends so as to open primarily beneath the ventricular outlets. The outlet component of the ventricular septum is not normally in the same plane as the remainder of the muscular septum. Defects involving the junction of the inlet and outlet components of the ventricular septum, therefore, are characterised by a degree of overriding of the aortic valve. The feature of these defects, as shown in

Figure 28-21 The cartoon shows shunting through a deficient atrioventricular component of the membranous septum—the so-called Gerbode defect. This is a true atrioventricular septal defect with separate atrioventricular junctions.

Figure 28-22 More usually, shunting from left ventricle to right atrium in hearts with separate atrioventricular junctions occurs initially through a perimembranous defect, as shown here, with further shunting across a deficiency of the tricuspid valve. Compare with Figure 28-21.

Figure 28-13, is that the muscular outlet septum, supporting the free-standing muscular subpulmonary infundibulum, becomes recognisable as a discrete entity, being malaligned relative to the rest of the muscular septum, and most usually occupying a position exclusively within the right ventricle, although the outlet septum can also be deviated into the left ventricle. In these settings, the orifice of

the aortic valve overrides the muscular ventricular septum (Fig. 28-23). Such defects opening between the outlets in the presence of aortic overriding and with the outlet septum deviated into the right ventricle are closely related to tetralogy of Fallot (see Chapter 36). The distinction between the two entities depends upon the presence or absence of muscular infundibular stenosis. The lesion with valvar overriding

Figure 28-23 The heart shown previously in Figure 28-13 has been sectioned to simulate the subcostal right oblique echocardiogram in B. The outlet septum is malaligned into the right ventricle. The cut has also passed through the aortic root, confirming that a good part of the aortic valve is supported in the right ventricle, and confirming the presence of overriding of the aortic valve. Note the unobstructed subpulmonary outlet. This is an example of the so-called Eisenmenger ventricular septal defect.

in the absence of obstruction to pulmonary flow is often described as the Eisenmenger ventricular septal defect.

As we have also discussed, the outlet septum can be deviated posteriorly into the left ventricular outflow tract. This usually produces subaortic obstruction (see Fig. 28-14), and is almost always associated with obstructive lesions of the aortic arch, either severe tubular hypoplasia or interruption. It would seem that the pulmonary valvar orifice should override the muscular ventricular septum in such defects. Because of the length of the free-standing muscular subpulmonary infundibulum, however, valvar overriding is rare, usually being seen only when the defect is doubly committed and juxta-arterial.²⁴

Irrespective of whether a perimembranous defect extends to open between the inlet or outlet ventricular components, or is large enough to open to all parts of the ventricle, a situation described as being confluent, the basic distribution of the axis for atrioventricular conduction is the same. In the normal heart, the penetrating component of the atrioventricular conduction axis passes through the central fibrous body, and branches on the crest of the muscular ventricular septum. Since the central fibrous body forms the postero-inferior margin of perimembranous defects, this will be the site of penetration of the axis. The landmark of the atrioventricular node, as in the normal heart, is the apex of the triangle of Koch. When the defect opens to the right ventricular inlet, the triangle may itself be displaced posteriorly, but its apex still serves as the guide to the site penetration of the conducting bundle. When the axis has penetrated through the central fibrous body, it is related to the postero-inferior rim of perimembranous defects. The precise relationship of its non-branching component to the septal crest depends upon the location of the defect. It is much closer to the crest when a defect opens to the

inlet, becoming more remote as the defect extends to open between the outlets.

Because perimembranous defects are closely related to the septal leaflet of the tricuspid valve, there is always the possibility that they may be closed by plastering down of the leaflet across the defect, with small ones being those most likely to close. Defects between the outlet components, particularly when complicated by malalignment, are unlikely to close by this mechanism. Neither are extensive inlet defects. A more frequent, and closely related, mechanism of closure is aneurysmal enlargement of fibrous tissue in the environs of the defect. Although often described as aneurysms of the membranous septum, it is unusual for the remnant of the membranous septum itself to be involved. In most cases, the grape-like lesions are sculpted from the underside of the leaflets of the tricuspid valve. On occasion, the tags can be more extensive hammock-like lesions, with cordal attachments to the septum (Fig. 28-24). The presence of tissue tags is an indication that defects may close spontaneously, and hence that there will be less necessity for surgical closure. On rare occasions, however, the tags can become sufficiently large as to balloon into the right ventricular outflow tract and produce subpulmonary obstruction.

Aneurysmal prolapse of the right coronary leaflet of the aortic valve can be found in the setting of perimembranous defects, particularly those opening between the outlets, when the outlet septum is markedly deficient. Sometimes the non-coronary aortic leaflet, and rarely the left, can also prolapse through the defect. Rarely, such valvar prolapse may produce partial or complete plugging of the defect, and result in spontaneous closure or a false sense of security that the defect is small when, in reality, it is a large defect. The prolapse can also result in aortic regurgitation.

Figure 28-24 A, This perimembranous defect, opening to the inlet of the right ventricle had been almost closed by the tissue tags (stars) derived from the leaflets of the tricuspid valve. Note the cordal attachments to the septum. B, The parasternal long-axis echocardiogram from a different patient shows the corresponding anatomy.

In all of these possible mechanisms of closure or diminution in size, contraction and fibrosis around the edges of the defect are additional contributory factors.

Muscular Defects

Defects with entirely muscular rims are also distinguished according to whether they open mostly to the inlet, mostly to the apical trabecular component, or mostly to the subpulmonary outlet as seen from the right ventricular side. Such defects can be multiple, particularly when in the apical trabecular septum, or can co-exist with perimembranous or juxta-arterial defects. Those opening to the right ventricular inlet will be covered to some extent by the septal leaflet of the tricuspid valve, and can then be difficult to distinguish from perimembranous defects opening to the inlet. For the defect to be muscular, a bar of muscle, which may be quite small, must interpose between the defect and the hinge points of the leaflets of the mitral and tricuspid valves (see Fig. 28-1). When a defect is perimembranous, or juxta-tricuspid and non-perimembranous, the leaflets of the mitral and tricuspid valves are in fibrous continuity in its postero-inferior margin (see Fig. 28-16). When the defect is muscular, or juxta-tricuspid and non-perimembranous, the atrioventricular conduction axis passes above, or anterosuperior, and will be to the left hand when viewed by the surgeon in the operating room. The bundle is always located postero-inferiorly when the defect is perimembranous, and hence will be to the right hand as viewed by the surgeon (Fig. 28-25).

Muscular defects in the apical trabecular septum are frequently large holes that tend to be found to one or other side of the septomarginal trabeculation. Not infrequently, a single opening, as viewed from the left ventricular aspect, is crossed by trabeculations to produce two, or more, openings when viewed from the right ventricle (Fig. 28-26). Multiple smaller muscular defects give the so-called

Figure 28-26 There seem to be three muscular defects opening to the anterior apical part of the right ventricle (arrows). In reality, this is but a single hole crossed by two septoparietal trabeculations.

Swiss-cheese septum. These may be particularly difficult to define, even in the postmortem specimen. Although the atrioventricular conduction axis is itself unrelated to muscular defects in the apical septum, the distal bundle branches may pass through the muscular septum between holes, producing pseudobifurcations.

Outlet, or infundibular, muscular defects are small and usually single, although they can be larger (Fig. 28-27). The superior rim of such outlet defects is the outlet septum, often attenuated, along with the sleeve of free-standing subpulmonary infundibulum, while the inferior muscular rim, which separates the defect from the membranous septum, is formed by fusion of the posterior limb of the septomarginal trabeculation with the ventriculo-infundibular fold. This muscular tissue separates the conduction tissue axis from the crest of the septum, thus providing protection from surgical damage by sutures placed in the postero-inferior edges of the defect. Small muscular defects close spontaneously simply by growth of the muscular structures surrounding them. As already discussed, they are almost certainly the most common defects undergoing spontaneous closure.⁹⁻¹²

Figure 28-25 The cartoon shows the crucial difference in disposition of the atrioventricular conduction axis when perimembranous as opposed to muscular defects open to the inlet of the right ventricle.

Doubly Committed Juxta-arterial Defects

The defect is termed juxta-arterial because it is directly related to both aortic and pulmonary valves (see Fig. 28-12), this feature underscoring echocardiographic recognition (Fig. 28-28). It is also because of this feature that both arterial valves frequently override the septum, giving a progressive spectrum of anomalies the end-point of which is double outlet left ventricle. Such hearts have also been termed double outlet both ventricles.²⁵ Prolapse of the aortic valvar leaflets is frequent with the juxta-arterial defect, albeit that, as already discussed, such prolapse can also lead to valvar insufficiency when a defect is perimembranous. The relationship of the atrioventricular conduction axis to

Figure 28-27 A, This defect opening to the outlet of the right ventricle has exclusively muscular rims. The superior rim is the muscular outlet septum, supporting the free-standing sleeve of infundibular musculature, whilst the postero-inferior muscular rim is formed by fusion of the posterior limb of the septo-marginal trabeculation (SMT) with the ventriculo-infundibular (vent-inf.) fold. B, The subcostal echocardiogram through the right ventricle from a different patient shows the corresponding anatomy.

the doubly committed defect depends on the morphology of its postero-inferior margin. A well-formed muscular rim (Fig. 28-29) separates the conduction axis from the postero-inferior margin of the defect. In contrast, the atrioventricular bundle is more at risk when the doubly committed defect is also perimembranous (Fig. 28-30).

Juxta-tricuspid and Non-perimembranous Defects

This rarest type of ventricular septal defect involves the inlet muscular septum along the tricuspid annulus but does not reach the membranous septum and therefore the aortic valve.²² In a four-chamber view, the defect may not show any features different from a perimembranous defect extending toward the inlet along the tricuspid valvar annulus. The tricuspid and mitral valves are in direct contact above the defect in a four-chamber view. The major distinguishing feature of the juxta-tricuspid and non-perimembranous defect from the perimembranous variety is seen in a parasternal long axis cut, which shows that the defect is some distance from the aortic valve. As discussed, the conduction axis is located at the anterior aspect of the defect along the postero-inferior margin of the intact membranous septum.

Morphogenesis

It is impossible to achieve normal closure of the embryonic interventricular communication until the right atrioventricular junction is connected to the right ventricle, and the subaortic outflow tract transferred to the left ventricle. Thereafter, the persisting interventricular communication is closed by tissue derived from various sources (see Chapter 3 for details). It is not closed specifically, however, by the interventricular membranous septum.

When the interventricular communication is closed, the septal leaflet of the tricuspid valve has yet to be delaminated from the muscular septum.¹⁸ There cannot, therefore, at this stage, be an interventricular component to the membranous septum. Perimembranous defects cannot be explained simply on the basis of failure of closure of the embryonic interventricular communication by the interventricular component of the membranous septum. It is more likely that the muscular septum is deficient in the environs of the closing plug of tissue, which is a consequence of insufficient area or volume. Deficiency of the different parts of the muscular septum then accounts for the diversity in position and orientation of perimembranous defects.

The formation of muscular defects is more easily explained. It is now established that, at least in the chick,²⁶ the muscular septum is produced by coalescence of embryonic trabeculations. Muscular defects, therefore, likely result from failure of the trabeculations to coalesce. This notion is now supported by the fact that, increasingly, such an arrangement is seen in association with ventricular non-compaction. When extensive, and involving the septum, such noncompaction produces the Swiss-cheese septum. Alternatively, there may be failure of fusion of the muscular septum with the free-standing septal component of the subpulmonary infundibulum, derived by muscularisation of the outflow cushions. Such failure of fusion of the infundibulum with the muscular septum and the septomarginal trabeculation gives a good explanation for the muscular defect opening between the outlets.

The doubly committed juxta-arterial defect is well explained simply on the basis of failure of muscularisation of proximal outflow cushions during division of the embryonic outflow tract. Because of the failure of formation of the muscular subpulmonary infundibulum, the defect is

Figure 28-28 The specimen (A) and corresponding echocardiogram (B) sectioned through a doubly committed and juxta-arterial defect in long-axis oblique plane reveals the fibrous continuity between the leaflets of the aortic and pulmonary valves that is the key to diagnosis of this type of defect. The star shows the crest of the muscular ventricular septum. The echocardiogram shows the prolapsed aortic valve, with the colour flow showing aortic regurgitation.

closely related developmentally to common arterial trunk (see Chapter 41).

PATHOPHYSIOLOGY

The pathophysiology of ventricular septal defect is determined by the size of the defect and the state of the pulmonary vascular resistance. The site of the hole between the ventricles has little influence. Between them, size and resistance govern the direction and magnitude of flow through the defect, and thus the clinical features and symptomatology.

Effect of Size

The size of the defect is crucial. Below a critical size, the defect itself presents a resistance to flow through it, which controls the magnitude but not the direction of the shunt.

Above this critical size, there is no appreciable resistance to flow. Both magnitude and direction of flow are then determined by the level of pulmonary vascular resistance. There is little data concerning this critical size. Some authorities have argued, unsupported by scientific investigation, that defects smaller than the aortic orifice are restrictive. Others²⁷ attempted to quantify the critical size by comparing the diameter of the defect with body surface area, suggesting that the key value was a diameter of 1 cm/m² body surface area, corresponding to an orificial area of approximately 0.8 cm²/m² body surface area. Defects having ratios smaller than this were restrictive, and produced minor or no haemodynamic changes. This suggests that the critical size is smaller than the aortic orifice, since a normal aortic valvar orifice is calculated to be approximately 2.0 cm²/m² body surface area. In practice, the judgement of the size of a defect is generally made on haemodynamic

Figure 28-29 A, In this doubly committed and juxta-arterial defect, there is an extensive muscular postero-inferior rim separating the margin of the defect from the tricuspid valve. Though the conduction axis is related to the postero-inferior margin of the defect, this muscular bar separates the atrioventricular conduction axis from the edge of the defect, thereby protecting it from injury when sutures are placed in the margin of the defect. B, In the corresponding echocardiogram obtained along the short-axis plane of the aortic valve, the leaflet of the aortic valve is in direct fibrous continuity with the leaflet of the pulmonary valve. Muscle separates the tricuspid and aortic valves along the postero-inferior rim of the defect. SMT, septomarginal trabeculation.

Figure 28-30 A, In this doubly committed and juxta-arterial defect (compare with Fig. 28-29), the hole extends postero-inferiorly so that there is fibrous continuity between the leaflets of the aortic and tricuspid valve, making the defect perimembranous. This means that the conduction bundle will be at potential surgical risk in the postero-inferior margin of the defect. B, In the corresponding echocardiogram obtained along the short-axis plane of the aortic valve, the right coronary sinus (RCS) of the aortic valve is entirely devoid of muscular support from the right ventricle. The leaflet of the right coronary sinus is in direct fibrous continuity (red star) with the leaflet of the pulmonary valve, and the leaflet of the non-coronary sinus (NCS) is in direct fibrous continuity (green star) with the leaflet of the tricuspid valve. LCS indicates the left coronary sinus.

grounds. When there is a left-to-right shunt, and no other associated anomalies such as pulmonary stenosis, a large defect is one that permits equalisation of systolic pressures in the two ventricles, and the defect is also unrestrictive. Since the right and left ventricles do not contract exactly

simultaneously, there is always some inequality in the ventricular pressures. Consequently, throughout the greater part of systole, the pressure difference will promote left-to-right shunting. During isovolumic relaxation, additional right-to-left shunting occurs, which is then cleared by the

subsequent diastolic left-to-right shunt, unless right ventricular ejection is obstructed.²⁸

A restrictive defect, therefore, is one in which right ventricular and pulmonary arterial systolic pressures are lower than those in the left ventricle and aorta. The size of such defects may vary from those that are just restrictive, allowing some elevation of right-sided pressures, to small defects in which the right-sided pressures are normal. In effect, defects can be considered either restrictive or unrestrictive. In those that are restrictive, there is then a continuum of size between those large enough to allow a serious haemodynamic disturbance, and those so small that there is only a small left-to-right shunt, with normal right-sided pressures.

Effects of Pulmonary Vascular Resistance

The effect of pulmonary vascular resistance on the flow through restrictive defects is always secondary to the size of the hole. The smaller the defect, the lower the flow through it. When defects are unrestricted, the pulmonary vascular resistance, and, to a lesser extent, systemic vascular resistance, is the controlling factor. When the pulmonary vascular resistance is low, the flow through the defect, and the flow of blood to the lungs, will be high. Such a high flow is not present at birth. It takes a finite time for the pulmonary resistance to fall from the high intrauterine to the normal postnatal levels, usually accomplished in the normal infant within the first 2 weeks of life.

This fall may be delayed and limited in its extent in infants with a large ventricular septal defect. Contributory structural factors include limited postnatal growth of the lungs, and limitation of the number of intra-acinar blood vessels. In addition, there is hypertrophy of the muscular coat of the intra-acinar arteries and veins (see Chapter 7). It is not entirely clear why growth of the lungs, and proliferation of pulmonary vessels, is limited. Muscular hypertrophy of the walls of the vessels is probably secondary to the increased pulmonary flow. Such high flow to the lungs leads to increased left atrial pressure, which is known to cause pulmonary vasoconstriction in experimental animals. If the vasoconstriction is maintained, vascular muscular hypertrophy will presumably occur. This delay in the fall of the pulmonary resistance means that the maximal haemodynamic effects of an unrestrictive defect may not be reached for some weeks after birth. The time and course, and the extent of the fall in pulmonary resistance, are all variable. The maximal flow through the defect is usually achieved between 1 and 6 weeks of age. This is usually enough to allow a very high pulmonary flow, but the fall in pulmonary vascular resistance may be so limited that little flow occurs through the defect. Such patients may escape detection until the effects of severe pulmonary vascular disease have become apparent.

Once it has fallen to its lowest value, pulmonary vascular resistance may increase again with the development of the pathological changes of pulmonary vascular disease.^{29,30} This usually occurs only in patients in whom the pulmonary arterial pressure is high from birth. In consequence, it is almost entirely confined to those with an unrestrictive defect. As the resistance rises, flow across the defect decreases. When pulmonary vascular resistance exceeds that in the systemic circuit, the flow through the defect will change from left to right to a flow from right to

left. Thus, the level of resistance determines the direction of flow. Secondary effects of severe pulmonary vascular disease include enlargement of the right ventricle and the pulmonary trunk, and dilation of the infundibular attachments of the leaflets of the pulmonary valve. These may cause detectable, but usually haemodynamically insignificant, pulmonary regurgitation.

When defects are restrictive, there is wide spectrum of restrictiveness. In many, the defect is so small that the pulmonary vascular resistance has little or no effect on the magnitude of flow through it. In others, the defect is restrictive, not allowing equalisation of pressures between the two ventricles, but is big enough to permit a significant elevation of right ventricular and pulmonary arterial pressures. In these defects, the level of pulmonary vascular resistance will play a significant, albeit subordinate, role in controlling the magnitude of flow of blood to the lungs. Between the two extremes of restrictive defects, there is a continuum of size and, therefore, of pathophysiological effects.

Effect of Obstruction of the Pulmonary Outflow Tract

All our discussion thus far has presumed an unobstructed pulmonary outflow tract. If there is co-existing obstruction within the right ventricular outflow tract, either valvar or subvalvar, then the resistance to ejection from the right ventricle will have a similar effect to elevation of the pulmonary vascular resistance. The flow through an unrestrictive defect, and thence flow to the lungs, will be limited in proportion to the severity of the obstruction. In restrictive defects, obstruction to the right ventricular outflow will result in elevation of right ventricular pressure, again in proportion to the severity of obstruction. The right ventricular pressure, in extreme cases, may come to exceed that in the left ventricle. As in unrestrictive defects, obstruction of the pulmonary outflow tract in the larger of the restrictive defects will also have a limiting effect on the magnitude of flow. There will be a reversal in the direction of the shunt in all cases where right ventricular pressure exceeds that in the left ventricle. Although pulmonary valvar obstruction may be present unequivocally from birth, subvalvar obstruction can be acquired.

Response of the Heart to Flow between the Ventricles

The cardiac effects of a ventricular septal defect depend initially on the magnitude of flow to the lungs. With florid pulmonary flow, usually in the setting of unrestrictive defects, left atrial and left ventricular end-diastolic volumes are increased, and left ventricular muscle mass is also increased. Studies of pressure and volume in the left ventricle demonstrate the marked increase in left ventricular work imposed by a large defect. This necessitates left ventricular hypertrophy as a compensatory mechanism. With extreme pulmonary flow, there is also an increase in right ventricular dimensions. Because of the elevated right ventricular pressure, there will be an even more marked increase in right ventricular work. This results in additional right ventricular hypertrophy. This may be one mechanism for the development of subvalvar pulmonary stenosis.

Left ventricular work is increased by restrictive defects in relation to the flow to the lungs, but the right ventricle is relatively spared. Consequently, there is left ventricular

hypertrophy, but little increase in right ventricular size or muscle mass. With elevation of pulmonary vascular resistance, or with development of right ventricular outflow obstruction, left ventricular work is diminished because of the decrease in left-to-right shunting and pulmonary flow. The elevation of right ventricular pressure then results in right ventricular hypertrophy, which dominates the picture.

The pathophysiological effects of a ventricular septal defect can, in three situations, result in congestive cardiac failure. The first is an unrestrictive defect with high pulmonary flow, when the compensatory mechanisms are insufficient to provide an adequate systemic flow. These compensatory mechanisms include recruitment of sarcomeres to operate at an optimal end-diastolic length, muscular hypertrophy of right and left ventricles, and increased catecholamine drive to the ventricles. Those circumstances are usually reached before the age of 6 months. The second situation occurs much later. It is encountered when the right ventricular myocardium has undergone degenerative changes as a consequence of long-term ejection against high resistance. This is found with pulmonary vascular disease, and with prolonged and severe obstruction to the right ventricular outflow tract. The third situation is when a ventricular septal defect is complicated by aortic regurgitation, imposing a further volume load on the left ventricle, outstripping the compensatory mechanisms as discussed above. It is most frequently seen in older children and adults.

CLINICAL FEATURES

Presentation

The typical murmur of a ventricular septal defect is rarely heard at birth, since it takes time for the pulmonary vascular resistance to fall from the high levels of fetal life, which are sufficiently high to limit the flow through even an unrestrictive defect to levels insufficient to provide an audible murmur. The diagnosis can now be made during fetal life by means of echocardiographic screening. Even when cases are diagnosed during fetal life, it is necessary to exercise caution, since many subsequently close spontaneously. Very few, if any, of those diagnosed during fetal life will have the full clinical picture at birth. If diagnosis is made in the neonatal nursery, it is almost invariably during examination of the baby just prior to maternal discharge. At the end of the first week of life, when many murmurs are detected, it is rare for the pulmonary vascular resistance to have fallen sufficiently for the child to be symptomatic. Symptoms, when they occur, are related to the high flow of blood to the lungs, diminished pulmonary compliance, and elevation of the left atrial pressure as a result of the high pulmonary flow. This initially causes tachypnoea, which progresses with the onset of congestive cardiac failure to give dyspnoea on effort, most obvious when the baby feeds. In a baby with a typical unrestrictive or large restrictive defect, the parents are likely to complain that feeds take progressively longer over the first month or two of life, and lead to rapid exhaustion of the baby. Not only is the feeding prolonged, but it does not provide sufficient caloric intake for weight gain. With the development of severe cardiac failure, the baby will become obviously dyspnoeic even at rest. Intercostal, subcostal, and supraclavicular recession are then readily seen. This increased work of respiration imposes an increased requirement for energy, which is not satisfied because of

the difficulty of feeding, a vicious circle resulting in failure to thrive. Failure to thrive is, indeed, an alternative mode of presentation in infancy. It occurs in those babies with defects large enough to allow high pulmonary flow, but in whom the size of the defect, or the level of pulmonary vascular resistance, prevents the development of intractable congestive cardiac failure. Another association with high pulmonary flow is an increased susceptibility to respiratory infection. The parents may complain that their baby has frequent chesty colds. It may be during such an episode that a murmur is noted, and that cardiac failure is precipitated.

A small and restrictive defect may be detected at any age by the discovery of a murmur. But such a defect will rarely, if ever, cause symptoms. When a defect is found in this fashion after the age of 1 year, it is highly unlikely that, in itself, it will ever cause congestive cardiac failure. No such assurance can be given when discovery occurs in early infancy. There is a further small group of patients with ventricular septal defect who escape detection in infancy. They present with diminished effort tolerance and cyanosis during middle childhood or adolescence. These patients usually have severe pulmonary vascular disease. Even careful history-taking fails to elicit evidence of symptoms during infancy. It is probable that at no stage did their pulmonary vascular resistance fall to levels that permitted sufficient left-to-right shunting to allow recognition of the defect.

Another alternative, and rare, presentation is with respiratory symptoms from bronchial compression caused by grossly enlarged pulmonary arteries. Typically, the right middle lobe bronchus is compressed, but the left main and upper lobe bronchuses may also be involved. This presentation is most frequently seen in patients with severe pulmonary vascular disease, or in those with so-called absent leaflets of the pulmonary valve.

Infants with holes between the ventricles, therefore, rarely present in the first days of life. In those with small restrictive defects, presentation is by the incidental discovery of a murmur, the child remaining asymptomatic. In those with large but restrictive defects, and with unrestrictive defects, the initial finding may be a murmur, but symptoms rapidly ensue. It may be the symptoms of dyspnoea and failure to thrive that call attention to the heart. Presentation occurs only at the point of recognition of a right-to-left shunt in those rare patients with irreversible vascular disease, who may also present because of respiratory problems.

Physical Examination

The appearance of the patient is again dependent on the magnitude of flow through the defect. Those with small and restrictive defects are generally entirely normal. With large restrictive defects, but without frank congestive cardiac failure, patients tend to be small and thin for their age, with evidence of dyspnoea such as intercostal recession. Chronicity is suggested by a depression at the insertion of the diaphragm. This depression is at the site described by Harrison, a general practitioner working in the English county of Lincolnshire over the turn of the nineteenth century, as a late effect of rickets.³¹ There will also be bulging of the left chest, indicating cardiomegaly. In presence of large unrestrictive defects, similar appearance of more severe degree will be seen without the evidence of chronicity. Cyanosis will not be seen except in those older patients with

severe pulmonary vascular disease or in those with severe obstruction within the right ventricular outflow tract.

A systolic thrill is felt in almost all patients, except those with tiny muscular or perimembranous defects. When a thrill is present, it is localised to the second, third, and fourth intercostal spaces at the left sternal border. If the thrill is maximal in the first intercostal space or higher, and yet the auscultatory features are otherwise typical of a ventricular septal defect, the likelihood is that the defect is doubly committed and juxta-arterial.³² There are usually no other palpable abnormalities in the presence of small restrictive defects. When the defect is large, with a high flow, the cardiac impulse will be hyperdynamic and the thrill may be more widespread. In presence of severe pulmonary vascular disease, the striking features are a localised left parasternal heave of right ventricular type and a palpable second sound. The peripheral pulses are normal. Abnormalities such as a pulse with high volume or absence of the femoral pulse should suggest an associated arterial duct or coarctation, respectively.

The most typical auscultatory finding, a loud pansystolic murmur localised to the second and third left intercostal spaces, was not accepted as being caused by a hole between the ventricles when Roger gave his initial presentation to the Académie de Médecine.¹ This murmur is typical of many ventricular septal defects with a left-to-right shunt, even when they are small and restrictive. The murmur starts with the first sound, and continues up to the second sound. If the murmur starts with the first heart sound but stops short of the second, the defect is likely to be a small muscular one closing in late systole. Large unrestrictive defects in infants sometimes give rise to a shortened ejection systolic murmur that is not accompanied by a thrill. It is said that a pansystolic murmur may continue past the aortic component of the second heart sound. This is rarely appreciated by the ear. Similarly, the ear usually does not detect any variation in the intensity of the murmur, although phonocardiography does show that the murmur is loudest during mid-systole. When flow to the lungs is limited by pulmonary resistance, the systolic murmur is abbreviated, and may be completely absent. In such cases, an early diastolic murmur of pulmonary regurgitation may be heard, as well as a pulmonary click. In patients who have excessive flow to the lungs, the flow through the mitral valve is sufficient to produce a mid-diastolic murmur at the apex. The presence of this murmur is taken to indicate that pulmonary flow is more than twice the systemic flow. In patients with no other signs of pulmonary vascular disease, the appearance of a high-pitched early diastolic murmur is highly suggestive of the onset of aortic regurgitation.

In the absence of pulmonary vascular disease, the heart sounds are normal. It is claimed that the second heart sound is widely split, with delay of its pulmonary component.³³ In our experience, this is rarely appreciated on auscultation, although it is seen on phonocardiography. The pulmonary second sound is louder in patients with pulmonary hypertension. In those with severe pulmonary hypertension, the increased intensity is easy to detect. In less severe cases, the fact that the second heart sound is audibly split at the apex indicates that the pulmonary component is louder than normal. Development of this finding during follow-up should alert to the possibility of development of pulmonary vascular disease. The second

heart sound becomes single once severe pulmonary vascular disease has developed.³⁴

INVESTIGATIONS

Electrocardiography

The electrocardiographic features are not specific for ventricular septal defect. As may be expected, they do reflect the haemodynamic state. In patients with large unrestrictive defects presenting with a high pulmonary blood flow in infancy, there will be a normal sinus rhythm, probably with tachycardia, a frontal QRS axis within the normal range for age, and biventricular hypertrophy. Finding a superior axis suggests multiple defects,³⁵ that the lesion is the ventricular component of an atrioventricular septal defect, or that an isolated perimembranous defect with separate atrioventricular junctions excavates extensively to open to the right ventricular inlet. Tall upright T waves over the right praecordial leads in infancy strongly suggest that the right ventricular pressure is at systemic levels. Cardiac rhythm and the QRS axis are usually normal in those with large restrictive defects after the first few months of life. The QRS pattern is that of left ventricular dominance, with deep Q waves over the left chest leads indicating left ventricular volume overload. The electrocardiogram may be normal in patients with small restrictive defects.

Serial electrocardiograms provide more prognostic information in the early months of life than does a single tracing. Large and unrestrictive defects maintain the biventricular QRS morphology, while the smaller defects show the normal diminution of right ventricular forces with age. At any age, the presence of pulmonary vascular disease, or severe obstruction to the right ventricular outflow tract, is reflected by right without left ventricular hypertrophy, and by right-axis deviation. Should aortic regurgitation complicate a small defect or, alternatively, occur in a patient with established obstruction of the right ventricular outflow tract, then the changes of left ventricular volume overload will come to dominate the picture.

Radiology

Once more, radiological findings reflect the haemodynamic state. The chest radiograph is usually normal in the first days of life. With the development of left-to-right shunting, the lung vascularity becomes plethoric. When flow to the lungs is large, as in unrestrictive defects, cardiomegaly is noted and pulmonary plethora is marked (Fig. 28-31). The cardiac contour in such infants has no specific features. The lungs tend to be hyperinflated with flattened diaphragmatic contours. Subsegmental or segmental collapse of the lower lobes, particularly the left lower lobe, is often seen. A markedly enlarged heart may compress the left main bronchus, causing collapse of the left lower lobe. When defects are restrictive, with only mild elevation of the pulmonary flow, the chest radiograph may appear normal.

The development and progression of pulmonary vascular disease are reflected in diminution of the peripheral pulmonary vascular shadows, leading to the classical pruning of the peripheral pulmonary arteries, seen best in older children and adults. This is accompanied by progressive overall reduction in cardiac size as the flow of blood to the lungs falls, but with characteristic enlargement of the pulmonary knob. When obstruction develops in the right

Figure 28-31 Frontal (A) and lateral (B) chest radiographs of a 13-week-old infant with a large ventricular defect. Note the increased pulmonary vascularity and nonspecific enlargement of the cardiac silhouette. The lungs are hyperinflated.

ventricular outflow tract, there is reduction in both central and peripheral pulmonary arterial shadowing, but enlargement of the pulmonary trunk is rare. When complicated by aortic regurgitation, there will be progressive enlargement of the heart, with the cardiac contour suggesting left ventricular dominance. As the prolapsed leaflet or leaflets of the aortic valve reduce the size of the defect, or may close the defect, there will be a progressive reduction in the prominence of pulmonary vascular markings.

Echocardiography

Cross sectional echocardiographic examination^{36–40} is now recognised as the technique of choice for diagnosis.⁴¹ Not only does the technique show the presence of a defect, it also permits its accurate localisation. Furthermore, because the defect should be identified in more than one plane, its size can be estimated. Perimembranous defects are recognised in long-axis, four-chamber and short-axis views,

with fibrous continuity between the leaflets of the tricuspid and mitral or aortic valves being the pathognomic feature. Perimembranous defects opening to the inlet of the right ventricle are recognised by cuts through the ventricular inlets (Fig. 28-32). The four-chamber sections will demonstrate continuity between the leaflets of the tricuspid to mitral valves via the central fibrous body, with loss of the usual off-setting of the hinge-points of the leaflets. A gentle sweep of the transducer from a four-chamber cut to a long axis cut will demonstrate the continuity of the leaflets of the tricuspid and aortic valves through the central fibrous body. In the so-called juxta-tricuspid and non-perimembranous defect,²² the defect is described as being at some distance from the aortic valve because it does not reach the central fibrous body. We initially believed that we had identified such a defect echocardiographically (Fig. 28-33). When the surgeon closed the defect, however, he discovered a muscular ridge separating the hinges of the tricuspid and mitral valves in the roof of the defect. Hence, the defect

Figure 28-32 This cross sectional echocardiogram (A), with a comparable specimen (B), shows the features of a perimembranous defect (D) opening to the inlet of the right ventricle. The tricuspid and mitral valves are attached to the septum at the same level (asterisk). LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle; VSD, ventricular septal defect.

Figure 28-33 Echocardiograms in apical four-chamber (A) and subcostal left ventricular outflow tract cut (B) show a defect (D). The defect is demarcated by the tricuspid and mitral valves that are in direct contact (*asterisk*). However, the defect is at some distance from the aortic valve annulus. It was considered a juxta-tricuspid non-perimembranous defect. At surgery, a thin muscle tissue was found between the defect and the tricuspid valve annulus, and the defect was a muscular inlet defect by definition. AV, aortic valve; LA, left atrium; LV, left ventricle; MV, mitral valve; RA, right atrium; RV, right ventricle; TV, tricuspid valve.

was surrounded by muscle, and opened to the inlet of the right ventricle—in other words a muscular inlet defect. It remains the fact, therefore, that we have still to identify a patient with a juxta-tricuspid and non-perimembranous defect, either in the clinical setting or at autopsy. Defects opening between the outlets are best identified in the subcostal right oblique section, which shows the muscular outlet septum as an interventricular structure immediately beneath the subpulmonary infundibulum (Fig. 28-34;

see also Figs. 28-13 and 28-23). This is evidence of the biventricular aortic connection.⁴²

The parasternal short-axis cut at the level of the aortic valve will similarly show this discrete outlet septum (see Fig. 28-34). When this feature is present, the parasternal long-axis section will usually demonstrate overriding of the leaflets of the aortic valve (Fig. 28-35). For those defects opening between the outlets, and associated with posterior longitudinal deviation of the outlet septum, usually in the

Figure 28-34 This echocardiogram in a short-axis plane through the aortic valve (AV) shows a perimembranous defect opening to the outlet of the right ventricle (RVOT). Note that the aortic valve is in direct contact with the tricuspid valve (TV) through the defect. The outlet septum separates the aortic valve from the pulmonary valve (PV). OS, outlet septum. Other abbreviations as in Figure 28-33.

Figure 28-35 This echocardiogram in a parasternal long-axis plane shows the features of a perimembranous defect (D). The aortic valve shows a mild degree of overriding. Ao, aorta; LA, left atrium; LV, left ventricle; OS, outlet septum; PV, pulmonary valve; RV, right ventricle.

Figure 28-36 This echocardiogram is taken in an apical four-chamber cut, showing the features of a muscular inlet defect (D). The hinges of the atrioventricular valves (asterisks) retain their normal off-set (double-headed arrow). Abbreviations as in Figure 28-32.

Figure 28-37 This echocardiogram, taken in an apical four-chamber plane, shows the features of a muscular defect (D) opening between the trabecular parts of the ventricles. The hinges of the atrioventricular valves (asterisks) retain their normal off-set. Abbreviations as in Figure 28-32.

setting of aortic coarctation or interruption, the parasternal long-axis section will be the optimal plane for diagnosis. Muscular defects opening to the right ventricular inlet are best seen in the four-chamber view, but retain the feature of atrioventricular valvar off-setting (Fig. 28-36). Large defects within the apical trabecular septum are identified in four-chamber and short-axis planes (Fig. 28-37), while muscular defects opening to the subpulmonary outlet are identified in short-axis or right anterior oblique planes from parasternal or subcostal approaches. The best view

with which to distinguish perimembranous from muscular outlet defects is the high-parasternal short-axis section. This cut demonstrates the presence or absence of continuity between the leaflets of the tricuspid and aortic valves. Small or multiple muscular defects in the apical muscular septum are those least likely to be visualised without the aid of colour flow mapping. Doubly committed juxta-arterial defects are recognised because of the continuity of the leaflets of the aortic and pulmonary valves in the roof of the defect, with absence of much of the subpulmonary

Figure 28-38 A doubly committed juxta-arterial defect seen in a parasternal long axis cut (A) with a comparable section in a heart from a different patient (B). In the echocardiogram, the defect is partly closed by the prolapsed right coronary leaflet (RCL) of the aortic valve. Note that the aortic and pulmonary valves are in direct contact through the defect. The star shows the crest of the muscular ventricular septum. PT, pulmonary trunk. Other abbreviations as in Figure 28-33.

Figure 28-39 A doubly committed juxta-arterial defect (D) seen in subcostal right anterior section. The aortic and pulmonary valves are seen in fibrous continuity (arrow). AV, aortic valve; LA, left atrium; PT, pulmonary trunk; RA, right atrium; RPA, right pulmonary artery; RV, right ventricle.

infundibulum. These features are seen in long-axis (Fig. 28-38; see also Fig. 28-28), short-axis (see Fig. 28-29), and subcostal right oblique views (Fig. 28-39). If present, prolapse of the aortic valvar leaflets will be visualised (Fig. 28-40; see also Figs. 28-28 and 28-38). By rotating the transducer to focus on the leaflets of the tricuspid valve, it is also possible to show whether a doubly committed juxta-arterial defect is perimembranous, or is separated from the central fibrous body by a muscular rim. This feature will best be appreciated from the parasternal short-axis section across the aortic valve. Cross sectional echocardiography also demonstrates the proximity of the defect to structures that may close it, such as aneurysmal formation of tricuspid tissue tags (Fig. 28-41; see also Fig. 28-24), or plastering of the tricuspid valvar leaflet tissue across the defect. Although transoesophageal echocardiography is not

usually necessary in the delineation of ventricular septal defect in childhood, it may provide crucial information when there is straddling or overriding of the tricuspid valve (see Chapter 33). Identification of the site of the ventricular septal defect at initial examination will also provide hard evidence on the rate of spontaneous closure for different types of defects in different sites.³

In addition to these specific diagnostic findings, the echocardiogram also reflects the haemodynamic state. Left atrial and left ventricular dilation are easily seen in infants with a high pulmonary blood flow, the left ventricle being hyperdynamic. With large unrestrictive defects, there will be a concomitant increase in right ventricular dimensions, while in small restrictive defects the ventricular size and performance may be normal. Further insight into the physiological state is obtained by studying the motion of the leaflets of the pulmonary valve. With high flow to the lungs, but low pulmonary vascular resistance, the motion is normal. When there is a high pulmonary vascular resistance, the closure line of the leaflets is flattened, and the a-dip disappears. The onset of aortic regurgitation is indicated by the appearance of diastolic vibration of the mitral valve, well appreciated in earlier times on the M-mode tracing, but now visualised directly with colour flow mapping. In this case, the cross sectional echocardiogram should show the abnormalities of the aortic valve responsible for the regurgitation. For example, a prolapsing aortic valvar leaflet may be demonstrated (see Figs. 28-28 and 28-40). Alternatively, perforations and vegetations associated with infective endocarditis may be identified. As might be expected, all the advantages of cross sectional echocardiography in diagnosis are accentuated when enhanced by three-dimensional reconstruction. Such techniques, while not yet generally available, have immense potential, as shown by the reports describing their value.^{43,44}

Doppler Interrogation

The complete evaluation of a ventricular septal defect includes not only an assessment of the size, site and number of defects, but also an estimate of the haemodynamic consequences. By using continuous wave Doppler ultrasound, it is possible to measure the velocity of flow across any ventricular septal defect. Then, by invoking the

Figure 28-40 The long-axis views (systole and diastole) of a doubly committed juxta-arterial defect from a transoesophageal echocardiogram shows prolapse of the right coronary leaflet (arrow) of the aortic (Ao) valve into the right ventricular outflow tract (RVOT). LV, left ventricle; RCL, right coronary leaflet.

Figure 28-41 This four-chamber cut shows a fibrous tissue tag (arrows) from the tricuspid valve (TV) partially closing a perimembranous ventricular septal defect (D). MV, mitral valve. Other abbreviations as in Figure 28-32.

Figure 28-42 This resonance image, taken so as to be in the plane of the muscular ventricular septum, shows a muscular inlet ventricular septal defect (D).

principles of the Bernoulli equation, it is possible to calculate the instantaneous peak systolic pressure drop between the ventricles. Assuming that the left ventricular peak systolic pressure is the same as the systolic blood pressure, the right ventricular systolic pressure can then be estimated. In the absence of any obstruction within the right ventricular outflow tract, this can be presumed to be equal to the pulmonary arterial systolic pressure.

Infants and children with congenital cardiac defects, including those with a ventricular septal defect, frequently have mild tricuspid insufficiency. In this situation, it is possible to estimate the pressure drop across the tricuspid valve and, therefore, to estimate the right ventricular and pulmonary arterial systolic pressures. A potential source of error arises when there is a shunt from left ventricle to right atrium through the defect via a deficiency in the septal leaflet of the tricuspid valve. In this situation, the regurgitant jet reflects the pressure drop between the left ventricle and right atrium.

Colour flow mapping has greatly facilitated the echocardiographic diagnosis of ventricular septal defect.⁴⁵ Its most important uses include accurate alignment of the Doppler beam with the flow of blood, thus enhancing accurate quantification of velocity, the detection of multiple ventricular septal defects, and the demonstration of shunting from left ventricle to right atrium. Colour flow mapping also plays a role in distinguishing innocent murmurs from those caused by very small ventricular septal defects.

Transoesophageal Echocardiography

Precordial cross sectional echocardiography detects the vast majority of even small ventricular septal defects. In a small number of patients, especially older children, adolescents, and adults, transoesophageal echocardiography may be required for complete assessment. This technique may also

be of particular value during the peri-operative period in the operating theatre and intensive care unit, especially to evaluate residual shunts. An important further use of transoesophageal echocardiography is to distinguish between a ruptured sinus of Valsalva and a perimembranous ventricular septal defect associated with aortic insufficiency. The technique is also indispensable when attempting closure of ventricular septal defects by interventional catheterisation because it allows precise positioning of the retention discs on either side of the defect. On-line three-dimensional echocardiography, at present, represents a growing area and is now being introduced as a routine clinical tool. Reconstruction achieved in this fashion can provide additional information about the morphological features of a ventricular septal defect.⁴⁶

Magnetic Resonance Imaging

As may be anticipated, magnetic resonance imaging clearly shows the location and structure of defects (Figs. 28-42 and 28-43; see also Fig. 28-14). Hardly ever is there a clinical indication for pre-operative morphological investigation of the defect unless echocardiography fails to visualise pertinent anatomical features of the defect. Phase-contrast velocity mapping, an accurate tool for the assessment of volumes of flow of blood, can be used to quantify pulmonary and systemic flows and the calculation of the left-to-right shunt. In addition, magnetic resonance imaging can be used for post-operative assessment of the ventricular volumes and function.

Computed Tomography

Computed tomography is indicated when the ventricular septal defect is complicated by or associated with the abnormalities of the airway or lungs, such as bronchial compression, atelectasis, or pneumonia. Contrast-enhanced computed

Figure 28-43 The features of a doubly committed juxta-arterial defect (D) are seen in this magnetic resonance image taken through the outlet of the ventricular septum. The aortic and pulmonary valves are in direct contact above the defect (asterisk).

tomography can also be useful when obstruction of the aortic arch is suspected, but the echocardiographic findings are inconclusive.

Nuclear Angiography

First-pass studies in nuclear angiography demonstrate the presence of either a left-to-right or a right-to-left shunt, and permit quantification of the ratios of systemic to pulmonary flows.^{47,48} Gated blood-pool scans allow assessment of left ventricular size and performance, but do not differentiate the different sites or type of defect. These techniques are largely replaced by magnetic resonance imaging, but can be of value in long-term post-operative assessment, particularly when performed in association with an exercise or stress-testing protocol.

Cardiac Catheterisation

Prior to the advances made in cross sectional echocardiography, catheterisation was an essential part of the assessment of patients having large restrictive and unrestrictive defects. It made possible the measurement of intracardiac pressures, particularly the pulmonary arterial pressure, along with quantification of the flow of blood to the lungs. This information made it possible to calculate the pulmonary vascular resistance. In addition, the technique provides confirmation of the interventricular location of the defect by the detection of a step-up in saturation of oxygen at ventricular level, or by visualisation of the passage of the catheter from right to left ventricle or to the aorta. If the defect is modified by abnormal attachments of the leaflets of the tricuspid valve, such that the shunt is from left ventricle to right atrium, then the step-up in saturation of oxygen is detected in the right atrium. This is also found when

a ventricular septal defect co-exists with an atrial septal defect, or when there is an atrioventricular septal defect. Cardiac catheterisation provides further information about the associated defects. Passage of the catheter from the pulmonary trunk to the descending aorta, for example, indicates the presence of a communication between these two arteries, usually an arterial duct.

The findings at catheterisation reflect the pathophysiology. Unrestrictive defects with a high pulmonary blood flow have similar pressures in right and left ventricles. With an unobstructed right ventricular outflow tract, and a low pulmonary vascular resistance, the pulmonary arterial systolic pressure will be similar to that in the aorta. The diastolic and mean pulmonary arterial pressures will be lower than aortic pressures. In such cases, a high flow to the lungs will be measured oximetrically, or in the past by dye dilution curves. In large but restrictive defects, the right ventricular and pulmonary arterial pressures will be lower than those in the left ventricle and aorta. The main current indication for cardiac catheterisation other than for interventional closure of the defect is to establish, beyond doubt, that patients suspected to have pulmonary vascular disease do have an elevation of pulmonary vascular resistance so great as to render them inoperable.

Angiocardiography

Although a case can still be made for performing catheterisation in order to take measurements and calculate shunts and pressures, it is now rarely necessary to perform angiography. In the past, the technique was directed to anatomical delineation of the defect itself, and to the diagnosis or exclusion of associated abnormalities. Left ventricular angiocardiograms were best for anatomical diagnosis. If still performed, it is best to choose an axial oblique projection.⁴⁹⁻⁵² The long-axis view is the best for demonstration of the different types of perimembranous defect (Fig. 28-44).⁵³ Doubly committed juxta-arterial defects will also be shown on this view, but demonstration of the lack of infundibular musculature separating the defect from the hinge-points of the leaflets of the pulmonary valve requires a right anterior oblique projection (Fig. 28-45). The long-axis view is again best for demonstrating muscular defects in the apical trabecular septum (Fig. 28-46). A muscular defect between the inlets is clearly demonstrated in the four-chamber view, while a muscular defect between the outlets is profiled in long axial or right anterior oblique projection (Fig. 28-47). If there is doubt about the site of the defect, the long-axis view is helpful, because defects opening to the right ventricular inlet appear behind the line of the anterior portion of the muscular septum. If performed, careful examination of the angiocardiograms should always be undertaken to exclude mitral regurgitation. In patients with pulmonary hypertension, a persistent arterial duct must always be excluded. This is frequently possible on the axial oblique left ventricular injection. When this is not the case, and echocardiography has not resolved the issues, aortography must be performed. A similar approach may also be necessary to exclude associated aortic coarctation. Retrograde aortography is important when aortic regurgitation is suspected. Right ventricular angiography is indicated when obstruction in the right ventricular outflow tract is

Figure 28-44 The different types of perimembranous defects seen in the long-axial oblique views. A, A defect opening to the inlet of the right ventricle (*arrows* delineate the septal leaflet of the tricuspid valve). B, A defect extending toward the inlet of the right ventricle (*arrows* delineate the anterior leaflet of the tricuspid valve). C, A defect extending toward the trabecular part of the right ventricle. Shunt flow (*arrows*) does not delineate the tricuspid valve orifice, which is denoted by *arrowheads*. Armonk, NY: Futura, 1997.)

found on cardiac catheterisation. This is best performed in the 45-degree head-up position using antero-posterior and lateral projections.

Left ventricular angiograms can be used for quantitative assessment of left ventricular function. Left ventricular end-diastolic volume is usually increased, and the ejection fraction is normal or increased. These indexes have prognostic significance but rarely, if ever, will the decision whether or not to opt for closure be influenced by these findings. Nowadays, it is rarely necessary to perform invasive studies in infants with ventricular septal defects. All the necessary

information required to determine the need for surgical treatment is provided by non-invasive tests.

DIAGNOSIS

The definitive diagnosis of isolated ventricular septal defect no longer depends upon cardiac catheterisation and angiocardiography but, as discussed above, is made with certainty in the majority of patients using cross sectional echocardiography. In many instances, nonetheless, the diagnosis can also be made from purely clinical

Figure 28-45 A doubly committed juxta-arterial defect in the right anterior (A) and lateral (B) views. The defect (*asterisk*) is in the outlet septum. The pulmonary and aortic valves are seen in direct contact above the defect. The initial shunt flow delineates the pulmonary valve in part A, while part B shows a different patient with pulmonary hypertension and a right-to-left shunt flow immediately below the pulmonary valve (*arrows*) and well above the tricuspid valve (*arrowheads*). AO, aorta; LV, left ventricle; PA, pulmonary trunk; RV, right ventricle. evidence, supported by the electrocardiogram and the chest radiograph. Thus, in an asymptomatic child over the age of 1 year, the typical physical signs, taken together with the chest radiograph and electrocardiogram, permit a confident diagnosis. This is not the case in infancy, particularly during early infancy. In this setting, a ventricular septal defect is frequently a component of a more complex lesion. It may also be difficult, on clinical grounds alone, to be certain whether the defect is isolated. For example, when a ventricular septal defect occurs in the setting of transposition, the flow to the lungs may be so high that cyanosis is not clinically apparent. Yet the thrill and murmur, and the radiographic and electrocardiographic features, may be compatible with an isolated lesion. In such patients, the response of blood gases to inhalation of 100% oxygen may indicate that the malformation is a complex one. Occasionally this test is misleading, particularly when the ventricular septal defect is found in the setting of a common arterial trunk. Echocardiography is crucial in differentiating isolated defects from more complex anomalies and should, therefore, be performed in all infants suspected of having a ventricular septal defect.⁵⁴ Although the clinical features may leave the diagnosis of isolated ventricular septal defect in doubt, the investigations when expertly performed leave little possibility of an alternative diagnosis. The only possible area of confusion is a ventricular septal defect so large that only a rim of septal tissue can be identified separating apical portions of the ventricles with distinctive right and left patterns. This condition is frequently misdiagnosed as double inlet to a solitary indeterminate ventricle. Although it may be suspected on angiocardiographic or

echocardiographic grounds that a rim of ventricular septum is present, this can only be confirmed by direct inspection (see Chapter 31).

COURSE AND PROGNOSIS

The majority of patients live normal lives.^{55,56} It is difficult, if not impossible, to give accurate figures for the proportion of defects that close spontaneously. A wide range of estimates have been reported. Studies from the 1970s cite closure in up to three-fifths of cases.^{57,58} Even when patients present in congestive cardiac failure, the size of the defect in some can diminish over the first year, either anatomically or to the point where it is restrictive and pulmonary arterial pressures are normal. When account is taken of smaller defects now diagnosed echocardiographically, the proportion is almost certainly higher, with perhaps up to nine-tenths closing.³ This is of little clinical relevance, since many of these represent trivial defects. In practical terms, among those with clinically significant defects, closure occurs in about one-quarter of patients, mostly in those with small muscular and perimembranous defects. Occasionally, even a large unrestrictive defect associated with clinical symptoms may close spontaneously. Closure usually happens during the first 2 years of life, but can occur at any age. Indeed, many defects close during fetal life.⁵⁹ As the defect becomes smaller, the murmur is said to lose its pansystolic nature, becoming shorter and decrescendo. These changes have value in predicting those defects that are about to close.⁶⁰ Even in the group of patients whose defects persist, most lead normal active lives with very little risk of a cardiac death before the age of 40 years.⁵⁸ In adults with small defects, with ratios of flow of less than 2 to 1, normal pulmonary arterial pressures, and no element of left ventricular hypertrophy, the outcome is reported to be excellent.⁶¹ In this series, the majority of patients remained free of any symptoms. Aortic regurgitation and endocarditis were infrequent, and arrhythmias, if occurring, were benign.

The longest follow-up is that provided by the First and Second Joint Studies on the Natural History of Congenital Heart Defects.^{55,62} For this entire group, the probability of survival at 20 years was 87%. Survival for those with trivial or small defects was equivalent to the general population. For those with moderate or large defects, irrespective of whether the defect has been closed, 89% and 67%, respectively, survived. Of those children admitted with a diagnosis of pulmonary vascular disease, just over half were alive 20 years later. Risk factors for death were related to the size of the defect, and the presence or absence of pulmonary arterial hypertension on admission to the study. Follow-up data underscored the importance of surgical closure during infancy if the ventricular defect remained unrestricted and pulmonary hypertension persisted.⁶³

Some children may develop infundibular stenosis, limiting the shunt, and eventually become cyanotic. They require management as for the child with tetralogy of Fallot (see Chapter 36). A few children may develop mid-right ventricular obstruction, creating a two-chambered right ventricle.

Up to one-sixth of infants develop congestive cardiac failure requiring medical treatment.⁶⁴ This almost always occurs during the first 6 months of life. Many of these children will not survive longer than 6 months unless the

defect is closed. Some are adequately controlled on medical treatment, and do not require closure as a life-saving procedure. Such infants frequently have pulmonary hypertension as a consequence of their large defects, and are at risk for the development of pulmonary vascular disease. They form the only reliably identifiable group of the 3% to 6% of all patients who develop this complication. Any infant with pulmonary hypertension persisting through the early months of life is likely to develop pulmonary vascular disease. This becomes established and irreversible in the majority before the age of 2 years.⁶³ Patients who have experienced little or no fall in pulmonary vascular resistance after birth form the remainder of the subjects at high risk. Tragically, this latter group may escape detection until cyanosis supervenes. It is important, therefore, to recognise that irreversible and progressive pulmonary vascular disease is present in the affected patients long before they become cyanosed. The prognosis of patients with ventricular septal defect and pulmonary vascular disease is poor, but survival into adult life is common. Death usually occurs before 40 years of age. In females with pulmonary vascular disease, pregnancy poses a particular risk. This is because loss of blood of even moderate degree, as may occur at delivery, can precipitate an irreversible state of low output. Women with this condition should be advised to avoid pregnancy. If they do not heed this advice, a difficult choice is necessary, since termination of pregnancy also carries a significant risk. On balance, unwanted pregnancies should be terminated. If the patient strongly wishes to continue the pregnancy, many can deliver safely with careful supervision,⁶⁵⁻⁶⁷ although the maternal mortality may be as high as 50%.

There are two other complications of isolated ventricular septal defect that may cause death before the age of 40 years. The first is development of aortic regurgitation.⁶⁸ This is reported to occur in up to one-twentieth of patients, albeit that others report a much lower incidence.^{60,69} It occurs most usually either when the defect is doubly committed and juxta-arterial, when more than seven-tenths may be affected,⁷⁰ or when the defect is perimembranous.⁷¹ It can also occur in the presence of muscular outlet defects when the muscular outlet septum is hypoplastic.⁷² Almost always it is the right coronary aortic leaflet that prolapses through the defect. In perimembranous defects, the non-coronary leaflet, and rarely the left, may also be involved. It is often recommended that surgical treatment be offered as soon as significant aortic regurgitation is recognised.⁷³ It is now known that the condition is well tolerated during childhood in the majority of patients. It can occasionally precipitate cardiac failure refractory to medical treatment during childhood, but this complication is more frequently encountered during adult life.

The second complication is infective endocarditis. The incidence is approximately 1 to 2 per 1000 patient-years.^{64,74-76} This represents a risk of approximately 1 in 10 of developing infective endocarditis before the age of 70 years.⁶⁵ It is more likely that infective endocarditis will be contracted after the age of 20 years, rather than in childhood or adolescence. The size of defect has no influence on its incidence.⁷⁵ Most patients who develop infective endocarditis nowadays are successfully treated. The lifetime risk of dying of infective endocarditis as a complication in the setting of isolated ventricular septal defect has been

computed to be of the order of 2% to 3%.⁶⁴ Closure of the defects does not eliminate the chance of contracting this infection. Indeed, it may initiate it.^{64,75} Avoidance of infective endocarditis cannot, therefore, be proposed as an indication for the closure of ventricular septal defects.⁷⁷ The problem also continues into adult life, with one-tenth of one series of patients having episodes of bacterial endocarditis.⁷⁸ These were adults with small defects. Recent data, summarised by the American Heart Association,⁷⁹ recommended that, as in previous guidelines, those with isolated acyanotic ventricular septal defects did not require antibiotic coverage, citing evidence that prior antibiotic coverage in this situation, was not universally effective, and that prophylaxis was only reasonable for patients with the highest risk of developing an adverse outcome.

MANAGEMENT

When presentation occurs in early infancy, the outcome is always in doubt until a precise diagnosis has been made by echocardiography. For example, an asymptomatic infant presenting with a murmur at 1 month of age may be in intractable heart failure by the age of 3 months. Similarly, spontaneous closure of ventricular septal defect may occur even when the defect has been large enough to cause cardiac failure in infancy. The prognosis must always, therefore, be guarded during the first few months of life. Asymptomatic infants should be closely followed using echocardiography to assess the anatomy and the gradient from the left to the right ventricle. Those who remain asymptomatic, with no signs or investigations suggesting pulmonary hypertension, require no treatment, including no measures against infective endocarditis. These infants have small restrictive defects. Infants with congestive cardiac failure should be treated medically. If the cardiac failure is intractable to medical treatment, then surgical intervention is indicated. These infants usually have unrestrictive defects. Intractability of the cardiac failure can be deemed to be present when, despite maximal medical treatment with diuretics and afterload reduction, the infant fails to thrive despite aggressive feeding regimes, including nasogastric tube feeding. Subsequent to closure, improvement in growth is almost universal.⁸⁰

Infants responding to medical treatment may have unrestrictive defects, but they usually have large and restrictive ones. In either event, the pulmonary arterial pressure will be elevated in early infancy but may fall to normal by 6 months of age should the defect become smaller. Closure is indicated in these patients if Doppler echocardiography fails to show a fall in right ventricular pressure to less than 60% of the left ventricular pressure by 5 to 6 months of age, and the baby is failing adequately to grow. This is because such babies are at risk for the development of irreversible pulmonary vascular disease. If the Doppler velocity indicates a lower right ventricular pressure, conservative management should be continued. A basic assumption behind this policy is that pulmonary vascular disease can be prevented or reversed in its early stages. It is not certain that this is possible in all cases. The above recommendations give the best chance of achieving this aim at present.⁸¹ It must be borne in mind that, in some patients, this policy will carry attendant risks for closing defects that would have closed spontaneously.⁸² At present, the balance

of the risks between corrective and expectant management appears to favour correction.⁸³ If, and when, more precise ways of predicting reversibility and irreversibility of pulmonary vascular disease are developed, this policy will be modified accordingly.

It is rare for closure to be required for a patient with an isolated defect after the age of 1 year. Occasional patients who have escaped detection, and who have a large left-to-right shunt and an enlarged heart, may need closure in childhood. Recently this conservative policy has been questioned in the light of excellent surgical results, particularly with the prospect of possibly preventing aortic regurgitation.⁸⁵ The question posed was, should all defects be closed? Despite cogent arguments of this type, most paediatric cardiologists and surgeons favour a conservative approach.

Aortic regurgitation, when it occurs, may be sufficiently severe to cause cardiomegaly or heart failure. In the latter instance, surgery should be performed at any age. If frank cardiac failure is not present, it is best, if possible, to defer surgery until adolescence or adult life, since it may be necessary to replace the aortic valve, or to perform a Ross operation. Such delay is not advisable in the setting of significant left ventricular dilation. In this situation, we would recommend operation on the basis of echocardiographic measurements. If the end-systolic dimension is greater than 50 to 55 mm in adults, and greater than 29 mm/m² body surface area in children, surgery is indicated even in the absence of symptoms.⁸⁴ Severe obstruction of the right ventricular outflow tract develops in up to one-tenth of patients.^{85,86} It always requires surgical treatment. If possible, corrective surgery should be performed. The best results are probably obtained if this complication is treated as soon as it is recognised.

Surgical and Catheter-based Management

When surgery is required as a life-saving procedure in early infancy, there are two options. The first is to band the pulmonary trunk, followed by correction at a later age. The second is to perform primary closure. Banding of the pulmonary trunk is a safe and effective palliative procedure.⁸⁷ When assessing the approaches, account must be taken of the cumulative risk of palliation and subsequent correction. In the best hands, this was shown some time ago to be below 10%,^{88–90} but this figure is now much too high when set against the excellent results of primary closure. Banding, furthermore, has its own complications, particularly the development of subvalvar pulmonary obstruction. This may contribute to the development of cyanosis with its attendant risks, which will make definitive surgery an even more complex undertaking. It is, therefore, advisable that the corrective operation should not be delayed beyond the second year of life. Patients with ventricular septal defect who have had banding of the pulmonary trunk also have an unduly high incidence of subaortic stenosis.⁹¹ It is not quite clear whether this is because the presence of the subaortic stenosis meant that banding was more likely to be needed, or because banding has a tendency to cause subaortic stenosis. In most centres nowadays, nonetheless, banding is reserved for small infants with multiple ventricular septal defects, and those with inlet defects where primary closure would carry a significant risk of damage to

the atrioventricular valvar tension apparatus or the conduction axis. Banding is rarely, if ever, indicated nowadays in patients beyond the age of 6 months.^{92,93}

Closure of an isolated ventricular septal defect can now be performed within the first 6 months of life, and results in the best centres now approach zero mortality.⁹⁴ This is clearly superior to the best results of a two-stage approach. The operation can be performed using a ventriculotomy or by a transatrial approach. The applicability of the transatrial approach depends upon the site of the defect. Doubly committed juxta-arterial defects, and multiple defects, present particular difficulties. Nothing is lost, even in these patients, by carrying out an initial transatrial exploration, since this allows accurate placement and, therefore, limits the extent, of the necessary ventricular incision.⁹⁵ Multiple defects present a particular challenge. Apical left ventriculotomy has been proposed as the best approach.^{96,97} An alternative is to use a large Dacron patch covering all the muscular defects.⁹⁸ Even with this approach, left ventriculotomy is not always avoidable, with a reported hospital mortality of 7.7%. The way forward is likely to be the combined use of surgery and catheter intervention.

More recently, catheter-based approaches, either using periventricular⁹⁹ or primary percutaneous techniques,^{100,101} have supplanted in many instances the traditional surgical approach requiring cardiopulmonary bypass. A variety of devices have been employed, beginning with the clamshell double umbrella device.¹⁰² Structural problems plagued this, and other, devices,¹⁰³ until the introduction of a nitinol wire mesh plug with retention discs, the so-called Amplatzer Muscular VSD Occluder (AGA Medical Corp) (Fig. 28-48). Data from the United States registry of patients with muscular ventricular septal defect undergoing closure with a device¹⁰⁴ shows that successful percutaneous implantation occurred in 87% of patients, including those requiring multiple deployments, with a rate of closure of 97% at 12 months. Complications occurred in 11% of patients, including two patients who died, giving a worrisome mortality of 3%. An individual experience in 50 patients with muscular defects reported no procedural

Figure 28-48 An Amplatzer Muscular VSD Occluder (AGA Medical Corporation). Note the two retention discs that support the central plug, which stabilises the implant across the ventricular septum.

complications.¹⁰⁵ A number of devices designed for other cardiac and intracardiac applications have been used to close perimembranous defects,^{103,106} but with an undue incidence of complications and residual shunting. The Amplatzer Membranous VSD Occluder was specifically designed to address anatomical concerns, particularly the possibility of causing aortic insufficiency. This self-expanding double-disc device, also made of a nitinol mesh, has been implanted successfully with great success, and provides a high rate of closure without producing significant aortic valvar dysfunction. Such implantation, however, has been associated with an unacceptable incidence of complete heart block, both acutely and in longer term follow-up.^{107,108} It may well be that devices designed specifically for closure of perimembranous defects may have a role in future, although it is difficult to see how such devices could avoid impinging on the atrioventricular conduction axis. We cannot recommend this procedure, therefore, for those with perimembranous defects except in truly exceptional circumstances.

Elective surgery for those having ventricular septal defects should aim to be corrective. Patients surviving the first 6 months of life with persisting pulmonary hypertension should have primary closure of the defect before the age of 1 year. Pulmonary vascular disease is rare before the first birthday. Its incidence increases thereafter,¹⁰⁹ and is more common in those with multiple defects, or when associated with a patent arterial duct. With early surgery, the incidence of pulmonary vascular disease should approach zero, which it has, for all practical purposes. The possible routes for closure are either transatrial, transaortic, or apical approaches.¹¹⁰ Similarly, those with a large left-to-right shunt who have escaped detection, or for other reasons have survived the first year of life, should be corrected at the first opportunity. In all patients, the only direct contraindication to surgery is the presence of established and severe pulmonary vascular disease. The initial assessment of pulmonary vascular disease is made from the haemodynamic data. Patients with a calculated pulmonary vascular resistance greater than 8 Wood units/m² body surface area are generally considered inoperable. In those with calculated resistances of between 4 and 8 Wood units/m² body surface area, it is not possible to say whether the pulmonary vascular disease has become irreversible. More information must be provided to permit rational decisions in these patients. The administration of 100% oxygen during cardiac catheterisation nearly always produces a fall in calculated pulmonary vascular resistance. The greatest fall occurs in the patients with the highest pulmonary vascular resistance. When breathing room air, patients with undoubtedly severe pulmonary vascular disease retain measurable reactivity in their pulmonary vasculature.¹¹¹ In the presence of severe pulmonary vascular disease, therefore, the demonstration of reactivity is not necessarily an index of operability. This casts doubt on the value of this test in the assessment of operability in patients with less severe elevation of pulmonary vascular resistance. Administration of 100% oxygen may be helpful in patients with pulmonary venous desaturation, since it should reverse the transient hypoxic vasoconstrictor response. Indeed, if such patients have a restrictive ventricular septal defect, administration of 100% oxygen can cause a prompt drop in pulmonary arterial pressure from systemic levels. Inhalation of nitric

oxide has been shown to cause a fall in pulmonary vascular resistance in patients with pulmonary hypertension of various causes, and it has become a useful test in differentiating those who are operable from those who are not.^{112,113} In doubtful situations, a lung biopsy may provide useful information.³⁰ In practice, perhaps because of the small and possibly unrepresentative sample, biopsy is prone to give misleading information. It is rarely used nowadays for clinical decision-making.

Elective surgery is also required when subvalvar pulmonary stenosis is present. Resection of the obstructing muscle will be necessary at the time of closure. The presence of aortic regurgitation poses greater problems. It has been suggested that closure of the defect in itself may limit the valvar regurgitation, this being most effective in doubly committed juxta-arterial defects.⁶⁸ Indeed, there is a case to be made for closing all doubly committed juxta-arterial defects as soon as they are diagnosed, even in those rare instances where there is neither congestive cardiac failure nor high pulmonary arterial pressure. Once aortic regurgitation has developed, it is rarely possible in our experience to avoid a direct attack upon the aortic valve. Initially this may be conservative, and good results have been reported in the short and longer term.^{114,115} Replacement of the aortic valve has been recommended as the best initial form of treatment, particularly when the valvar leaflets are deformed.¹¹⁶ The balance of the evidence leads us to recommend an initial conservative approach wherever possible, with replacement only where this has failed or is impossible.

Course after Surgery

Subsequent to correction, the majority of patients live virtually normal lives and have normal exercise capacity.¹¹⁷ The clinical condition of almost nine-tenths of the patients is graded as good or excellent on follow-up examination. Of the remaining patients, very few are still classified as poor, whereas such a classification is frequent prior to surgery.^{55,56,80} A significant cause of morbidity and mortality is pulmonary vascular disease. When this is established, it usually progresses inexorably despite a corrective operation. This complication is avoided by early corrective surgery.¹¹⁷ Late post-operative exercise testing confirms the improvement after correction, again pointing to the advantage of early surgery.¹¹⁷

Disturbances of cardiac rhythm occur in perhaps one-twentieth of patients following corrective surgery,^{55,62,63} with some still suffering complete heart block. Even with precise knowledge of the conduction tissues, surgical heart block does still occur, although today it is extremely rare, with less than 1% of children affected. Should the complication occur, it requires the insertion of an artificial pacemaker, with its attendant morbidity.¹¹⁸ Permanent pacing should certainly be provided if the patient remains in congestive cardiac failure with a slow heart rate. When Stokes-Adams attacks occur, or if 24-hour monitoring of the electrocardiogram demonstrates prolonged period of asystole, episodes of ventricular tachycardia, or ventricular fibrillation, then even if the patient is asymptomatic, it is probably best to insert a pacemaker. In practice, a slow heart rate of 30 to 40 beats per minute at any time of the day is frequently used as a relative indicator for pacing. Transient heart block after surgery may predispose to late sudden death.⁷⁷

The Second Natural History Study showed a higher prevalence of both serious arrhythmias and sudden death in this setting.⁶² It follows that 24-hour tape monitoring is mandatory in all patients with heart block following surgery for ventricular septal defect, even when this resolves spontaneously. This investigation should be repeated periodically during follow-up. In the absence of symptoms, it should be performed at yearly or 6-monthly intervals. Monitoring should also be performed in patients with post-operative ventricular ectopic beats. There is some suggestive evidence that these, by triggering a life-threatening ventricular arrhythmia, may be responsible for sudden death.^{119,120}

Intraventricular conduction disturbances are seen in the majority of patients who have had open heart surgery. Right bundle branch block is certainly seen following repair of ventricular septal defect, be this performed transatrially or by the ventricular route.^{95,121} When this is an isolated phenomenon, it is not a prognostic sign. When it is associated with left-axis deviation and a prolonged PR interval (see Chapter 19), it may well be a precursor of late complete heart block, particularly when the post-operative period has been complicated by a period of transient complete heart block.¹²² In these patients, and in those where the right bundle branch block and left-axis deviation are not associated with a prolonged PR interval, intracardiac electrophysiological studies may assist in predicting the outcome.¹²¹ The prognostic significance of all these changes for the occurrence of sudden unexpected death remains uncertain.¹²⁰ Close surveillance with 24-hour tape monitoring is a wise precaution. As with complete heart block, there are no generally accepted criteria for the insertion prophylactically of a pacemaker.

Crucial to the long-term outcome in patients with intraventricular conduction disturbances is the site of interference with the conduction tissues. If this is central, that is, within the atrioventricular bundle, the risk of complete heart block is greater than if the damage is solely within the peripheral bundle branches. While intracardiac electrophysiological studies (see Chapter 19) have been suggested as being helpful, this is not always the case.¹²⁰ Atrial arrhythmias may occur if there is damage to the sinus node, for instance, during cannulation, but these are a rare occurrence nowadays following surgery for correction of ventricular septal defect.

The other common complication is a residual ventricular septal defect.^{55,110} In general, such residual defects are of little haemodynamic significance.¹¹⁷ Occasionally they will be large enough to permit a considerable residual left-to-right shunt. When this results in congestive, or persistent, cardiac failure, closure is indicated. Frequently this may be addressed with catheter-based approaches.¹²³ In the presence of a residual ventricular septal defect, lifelong prophylactic measures against infective endocarditis are still recommended.⁷⁹ These measures should be continued even when the operation appears to have been totally successful.

Patients undergoing surgery for ventricular septal defect are at risk for all the complications associated with open heart surgery performed for any reason, including cerebral damage, renal damage, postpericardotomy syndrome, pulmonary complications, and so on. The majority of patients, however, suffer no ill-effects, are improved and go on to lead normal lives. This they should be encouraged to do. Although it is too early to predict the ultimate lifespan of

such patients, organisations such as the armed services and the police force can be prevailed upon to accept recruits who have undergone closure of a ventricular septal defect. It is also the case that those who survive into adulthood without the need for closure can continue to pose a problem, albeit at low risk.^{61,63} In one cohort of adult patients,⁷⁸ although half had no complications over many years, and spontaneous closure occurred in one-tenth, serious complications were encountered in one-quarter. The malformation, therefore, is not entirely benign.

ANNOTATED REFERENCES

- Soto B, Becker AE, Moulart AJ, et al: Classification of ventricular septal defects. *Br Heart J* 1980;43:332–343.
This classification with obvious clinical relevance was based on study of hearts with concordant atrioventricular and ventriculoarterial connections. The ventricular septum itself was viewed as having muscular and membranous portions, the muscular septum itself being divided into inlet, trabecular, and outlet components. Defects observed in the area of the membranous septum were termed perimembranous, distinguishing them from muscular defects and those in the area of septum subjacent to the arterial valves, termed subarterial infundibular defects. Perimembranous defects could be found extending towards the inlet, apical, or outlet components of the right ventricle. Muscular defects were found opening to the inlet, apical trabecular, and outlet components of the right ventricle. These observations form the basis of classifying such defects in clinical practise.
- Soto B, Ceballos R, Kirklin JW: Ventricular septal defects: A surgical viewpoint. *J Am Coll Cardiol* 1989;14:1291–1297.
This anatomical study categorised ventricular septal defects from a surgical viewpoint. The defects were classified as being conoventricular, in the right ventricular outlet, in the inlet septum, or in the trabecular septum, with each category having several subcategories. Emphasis was placed on the relations of the defects to the left ventricular outflow tract. The borders of the ventricular septal defects were described in detail, with use of the prefix juxta- to indicate the immediate adjacency of the defect to a structure such as the tricuspid valve. Taken together with the classification discussed above, this provides the foundation of the terminology used today.

These studies utilised cross sectional echocardiography to identify and classify ventricular septal defects. Multiple precordial and subcostal echocardiographic planes are described. Defects visualised were classified on the basis of the structures which formed their margins, and correlations made angiographically, surgically, and pathologically. Echocardiography was reliable in identifying subaortic, inlet, small, moderate, and large subtricuspid, large subpulmonary, and large central and apical muscular ventricular septal defects. These studies describe the initial views used today in routine clinical practise to image and classify ventricular defects.
- Chen FL, Hsiung MC, Nanda N, et al: Real time three-dimensional echocardiography in assessing ventricular septal defects: An echocardiographic-surgical correlative study. *Echocardiography* 2006;23:562–568.
This study examines the potential value of real time three-dimensional echocardiography in accurately and quantitatively estimating the size of ventricular septal defects, correlating observations with surgical findings. The technology offered intra-operative visualisation of ventricular defects to generate a virtual sense of depth. From left ventricular en face projections, the position, size, and shape of the defects could accurately be determined to permit quantitative examination of dynamics. This study underscores this as a potentially valuable clinical tool to provide imaging for surgical and catheter-based interventions.

The Natural History of Congenital Heart Defects studies were the first significant multicentric investigations of outcomes for a variety of congenital cardiac lesions commonly seen in practise. These studies set the goal posts for the definition of severity, and the impact at the time of medical and surgical therapies. They became, and to a large extent remain, the basis for the decisions we make as paediatric cardiologists.

Long-term outcomes are summarised for those patients with a ventricular septal defect requiring surgical correction and those needing medical management alone. Outcomes are good in childhood through adulthood. We learn however, that the lesion in a small minority of adults does cause disability, cardiac failure, disturbances of rhythm, and endocarditis.

Erratum in *Circulation* 2007;116(15):e376–377.

The American Heart Association has recently changed its recommendations for prevention of endocarditis. These recommendations are very different from what has been applied in clinical practise for the last 3 decades. The reasons for these changes are presented. Note is made that the risk of endocarditis in any individual patient has not changed, just as its prevention with so-called endocarditis prophylaxis has not been effective. This should now be limited to those at the highest risk.

This series of papers summarises the applications of interventional techniques in the management of ventricular septal defects. Periventricular closure avoiding cardiopulmonary bypass, catheter laboratory based closure for native or unoperated defects, and the management of residual defects after surgery are presented. Technical success in the muscular defect is well over 90%, with excellent medium-term outcomes. The management of the perimembranous defect, however, eludes the interventionalist. While it can be closed, conduction complications make it less attractive at present.

Hypoplasia of the Left Heart

GIL WERNOVSKY, TROY E. DOMINGUEZ, PETER J. GRUBER, and ROBERT H. ANDERSON

Rather than being a single lesion, the entity usually described as hypoplastic left heart syndrome is a group of conditions with characteristic anatomical, physiological, and clinical properties. The earliest grouping of these features was made by Lev,¹ but he described the syndrome as hypoplasia of the aortic tract. Hypoplasia of the left heart is not always the same as aortic atresia or hypoplasia, since the aortic lesions can exist with a left ventricle of normal size, particularly when the aorta takes its origin from the morphologically right ventricle. As far as we are aware, it was Noonan and Nadas² who first used the term hypoplastic left heart syndrome. This is the term now generally accepted for description, despite the concerns that some have with regard to the definition of a syndrome. Geneticists define a syndrome as involving organs of several systems. Patients with the classical picture of hypoplasia of the left heart rarely have syndromic problems elsewhere in their bodies. If we wish to be specific, therefore, it is better to use hypoplasia of the left heart to describe the anatomical features of the entity to be discussed in this chapter. It is most unlikely, nonetheless, that those who diagnose and treat the entity will call it anything other than hypoplastic left heart syndrome, so we anticipate that the classical term will retain its currency.³

Although the combinations of anatomical lesions that constitute the syndrome are variable, the features when seen together are unmistakable. Thus, the syndrome includes the majority of cases of aortic atresia, and most cases of atresia of the left atrioventricular valve. Aortic atresia, nonetheless, when associated with deficient ventricular septation, can be found with a left ventricle of normal size. In these cases, the aorta may be in potential connection with the morphologically left ventricle. The atretic aorta may also be connected potentially to the morphologically right ventricle when the ventriculo-arterial connections are essentially discordant. In the latter setting, of course, the morphologically left ventricle is dominant rather than hypoplastic. In most of the cases of left atrioventricular valvar atresia with right hand ventricular topology, it is the left ventricle which is hypoplastic. Patients with hearts of this type fall within the group of classic cases when the ventricular septum is intact. When both arteries take their origin from the morphologically right ventricle in this setting, the aorta may be of good size despite the left ventricular hypoplasia. Furthermore, should the ventriculo-arterial connections be discordant, the left ventricle can again be hypoplastic. With such discordant ventriculo-arterial connections, the small left ventricle is in potential communication with the pulmonary trunk rather than the aorta. In the rare instances of this combination existing with an intact

ventricular septum, the combination will present clinically as pulmonary atresia, although the ventricular morphology is more representative of hypoplasia of the left heart. The left ventricle, aortic valve, and ascending aorta may all also be hypoplastic in the context of atrioventricular septal defect with common atrioventricular junction when there is right ventricular dominance. Patients with this combination are discussed in Chapter 36. In most of the cases initially studied by Noonan and Nadas,² aortic coarctation was the major anatomical feature, although the left ventricle was described as being hypoplastic. It is questionable whether such cases would nowadays be considered as examples of hypoplastic left heart syndrome, albeit that examples of the classical syndrome are held to exist with mitral and aortic valves of normal dimensions relative to the co-existing hypoplasia of the left ventricle. Some, therefore, describe these cases as a complex rather than a syndrome, and maintain that biventricular repair is possible following simple relief of any obstruction within the aortic arch and descending aorta.⁴

It follows from all the above discussion relating to different morphological patterns that there are major difficulties in providing an all-encompassing anatomical definition for hypoplasia of the left heart. It is more realistic, therefore, to analyze the unifying haemodynamic features. In physiological and clinical terms, hypoplasia of the left heart can be defined as the situation in which the systemic circulation is dependent on the morphologically right ventricle in the setting of atresia or severe hypoplasia of the aortic valve.⁵ For the purposes of this chapter, we will follow this definition, dealing exclusively with those lesions having a small morphologically left ventricle, an intact ventricular septum, and either atresia or critical stenosis of the aortic valve.

EPIDEMIOLOGY

Before fetal echocardiography routinely became a part of antenatal screening, the reported incidence of the hypoplastic left heart syndrome ranged from 0.16 to 0.36 per 1000 live births.^{6,7} In many countries, screening to establish normality of the four cardiac chambers is now routinely performed during antenatal ultrasonography, and the diagnosis of hypoplasia of the left heart is often made by non-cardiologists. Some parents, learning of the diagnosis prior to 20 weeks of gestation, will opt for termination of the pregnancy. This contributed, in some areas of the world, to a decline in the number of neonates born with the syndrome.⁸ In this respect, although the syndrome is not a common form of congenital cardiac disease, in the past it

generated a large proportion of the cardiovascular mortality occurring in the first month of life, since prior to the late 1980s, there was no treatment for the condition. It remains to be seen, with the improvements in surgical treatment to be discussed in this chapter, whether the observed decline in incidence because of termination of pregnancy will continue. In support of this speculation, a recent report from the United Kingdom demonstrated a reduction in the rate of termination of pregnancy of 50%.⁹

Of those surviving to term, two-thirds are male. It has been estimated that the risk of recurrence in siblings is 0.5%, with a risk of 2.2% for the occurrence of other congenitally malformed hearts.¹⁰ The syndrome can occur in the setting of Turner's syndrome, or its mosaic variant. It can also accompany Noonan's syndrome, microdeletion of chromosome 22q11, Holt–Oram syndrome, Edward's syndrome, and Jacobsen syndrome, and can be found with other chromosomal abnormalities, including trisomy 13, trisomy 18, and deletions of chromosomes 4q, 4p, 11q, and 18p. It has also been associated with different mendelian syndromes, but without a robust genetic association. With the advent of fetal echocardiography, it has become evident that recurrence of obstructive lesions in the left heart is particularly high in mothers referred with a family history of congenital cardiac disease. Such observations support a genetic predisposition to the development of such lesions. Epidemiological evidence in favour of this notion was provided by the Baltimore–Washington infant study.¹¹ It is also increasingly recognised that first-degree relatives of probands with hypoplasia of the left heart are at increased risk of less severe abnormalities of the left heart. In two recent reports from the United States, a bicuspid aortic valve was identified in 5% to 11% of first-degree relatives of affected probands.^{12,13}

AETIOLOGY

The aetiology of hypoplasia of the left heart is unknown in most instances. Associations with chromosomal or extra-cardiac defects are inconsistent, but more common than with many other forms of congenital cardiac malformations. Thus far, they have failed to refine our understanding of the genetic precursor of the disease, although recent work suggests that the basic helix-loop-helix transcription factors may play a role.¹⁴ Most current theories on the aetiology of hypoplastic left heart syndrome are based on autopsy findings, along with echocardiography, particularly fetal echocardiography. It is examination of the heart during the latter trimesters of gestation that has better enabled us to define its normal and abnormal development. In those eventually developing the syndrome, evidence of impaired growth of the left ventricle has been associated with diminished inflow or obstruction to outflow, although this does not become obvious until after 20 weeks of gestation.¹⁵

Experiments using chick embryos showed that hypoplasia of the left ventricle could be produced following intervention to occlude the mitral valve.¹⁶ This is unlikely to underscore development of the syndrome in humans, as mitral stenosis occurring as a primary lesion results in enlargement, rather than hypoplasia, of the left atrium. Displacement of the primary atrial septum has been noted in autopsied specimens,¹⁷ and has been presumed potentially to reduce flow through the inferior caval vein via the

oval foramen to the left atrium and left ventricle, resulting in left ventricular hypoplasia. The displaced septum could equally be the consequence of the ordered flow. Indeed, studies of flow during fetal life suggest that it is likely that the ventricular problem occurs first.¹⁸ Obstruction to the outflow from the left ventricle is always present, and it, too, has been implicated as an aetiological factor.¹⁹ Ventricular endocardial fibro-elastosis is prominent when the mitral valve is patent. In these patients, there can be little doubt that the high left ventricular pressure, particularly in diastole, is an important additional aetiological factor in the development of the endocardial ischaemia and scarring. In the light of the varied anatomical findings to be described below when the left ventricle is hypoplastic, it is unlikely that a solitary aetiological factor unifies their development. The familial occurrence of obstructive lesions in the left ventricular outflow tract and aortic arch, nonetheless, suggests that ongoing genetic advances will provide additional aetiological insights.

ANATOMY

Overall Structure

Hypoplasia of the left heart is usually found in the setting of usual atrial arrangement with concordant atrioventricular and ventriculo-arterial connections (Fig. 29-1), with absence of the left atrioventricular connection in some instances (Fig. 29-2). The combination should be anticipated to exist in the mirror-imaged format. There is usually obstruction to the left ventricular inflow and outflow, but this is variable. At the extreme, the left ventricular cavity may be no more than a slit in the postero-inferior wall of the ventricular mass (see Fig. 29-2).

While the anatomist can discover small ventricles by dissecting between the delimiting coronary arteries, it is almost impossible to determine morphologically when the left ventricle is to be considered hypoplastic in patients

Figure 29-1 The classic form of hypoplasia of the left heart, with marked left ventricular mural hypertrophy (arrow).

Figure 29-2 In this heart, which also had aortic atresia, there is absence of the left atrioventricular connection (*green dotted lines*). The left ventricle is no more than a slit in the postero-inferior margin of the ventricular mass.

with aortic valvar stenosis rather than atresia. Some of these hearts show obvious fibro-elastosis in the small ventricle and certainly fulfill the anatomical criteria for the syndrome (Fig. 29-3).

Under other circumstances, the ventricle may seem hypoplastic, but the morphologist will be unable to judge its ability to maintain an effective systemic circulation during life. It is the existence of such small left ventricles, in which the dimensions of the aortic and mitral valves are in keeping with the dimensions of the ventricle itself, which

Figure 29-3 In this heart from a patient with critical aortic stenosis, the right ventricle is apex-forming, and the hypoplastic left ventricle has an obvious fibro-elastotic lining. This is an example of hypoplastic left heart syndrome.

Figure 29-4 This picture shows the atrial septum in a heart with hypoplasia of the left ventricle. The atrial septum is intact, the flap valve being fused with the left atrial aspect of the rims of the oval fossa.

underscore the suggestion that some forms of the syndrome can be corrected in biventricular fashion without the need for surgery on either valve, hence the description of the so-called hypoplastic left heart complex.⁴

Typically, the left ventricular walls are hypertrophied (see Fig. 29-1). Indeed, the mass of the left ventricle may rarely be increased rather than decreased, despite the cavity hypoplasia. The left atrium is usually small (see Fig. 29-2). In typical cases, there can be hypertrophy of the left atrial walls, and some patients can be seen with an enlarged atrium, particularly the appendage. Left atrial endocardial fibro-elastosis is rare. In up to one-tenth of patients, the atrial septum will be intact (Fig. 29-4). In some of these patients with an intact floor to the oval fossa, while the pulmonary venous connections are normal, the pulmonary venous drainage can be abnormal because of the presence of a so-called levo-atrial cardinal vein, or because of fenestration of the walls that usually separate the left atrium from the cavity of the coronary sinus. This provides an overflow for the left atrial return. In other circumstances, however, there is no such overflow when the atrial septum is intact. The resulting increase in left atrial pressure then produces increased left atrial hypertrophy, along with changes in the lungs, including arterialisation of the pulmonary veins (Fig. 29-5) and lymphangiectasia, with a cobblestone appearance of the pulmonary surfaces seen at autopsy (Fig. 29-6). This is a bad prognostic feature. In most instances, however, the oval foramen is patent and does not obstruct flow from left to right, albeit that the primary atrial septum is frequently deviated into the left atrium (Fig. 29-7).¹⁷ Anomalous pulmonary venous connections are seen in a small proportion of patients, with supracardiac drainage being most often encountered.

Obstruction of Inflow to, and Outflow from, the Left Ventricle

In almost all cases, the mitral valve is either stenosed or atretic. In the presence of mitral stenosis, all components of the valve contribute to the obstruction (Fig. 29-8). When atretic, the mitral valve may be imperforate, or absent

Figure 29-5 In this heart from a patient with hypoplastic left heart syndrome, the atrial septum is intact. Note the hypertrophied walls of the left atrium. As shown in the inset, histology revealed arterialisation of the pulmonary veins. (Courtesy of Dr Andrew Cook, Great Ormond Street Hospital, London, United Kingdom.)

Figure 29-6 This image shows the right lung from the patient whose heart is shown in Figure 21-5. There is an obvious cobblestone appearance of the pulmonary surface, which is due to marked lymphangiectasia. This is a bad prognostic feature. (Courtesy of Dr Andrew Cook, Great Ormond Street Hospital, London, United Kingdom.)

together with the left atrioventricular connection (see Figs. 29-2 and 29-7). Left ventricular endocardial fibro-elastosis is seen only when the mitral valve is perforate (see Figs. 29-3 and 29-8). Obstruction of the left ventricular outflow tract is an invariable feature. Aortic atresia, as with mitral atresia, can result from an imperforate valve, but more usually there is no evidence of persisting leaflets at the ventriculo arterial junction, fibromuscular tissue interposing between the ventricular cavity and the blind-ending aortic root (see Fig. 29-1). The aortic root itself is usually markedly hypoplastic, with the ascending aorta serving only as a conduit to feed

Figure 29-7 This heart with hypoplasia of the left ventricle and absence of the left atrioventricular connection (green dotted lines) has been sectioned in four-chamber fashion, and is photographed from behind. Note the deviation of the flap valve of the atrial septum away from the infolded superior rim of the oval fossa, further diminishing the volume of the hypoplastic left atrium.

Figure 29-8 In this example of hypoplasia of the left heart, sectioned in four-chamber fashion, the mitral valve is stenotic, with shortened cords and dysplastic leaflets. Note the fibro-elastotic lining of the hypoplastic left ventricle.

the coronary arteries. The components of the arch itself are variably hypoplastic, including the ascending component.²⁰ When the outflow tract is patent, the aortic leaflets are thickened and dysplastic (see Fig. 29-3). Rarely, they may be absent, with a stenosing ring seen at the ventriculo-arterial junction, similar to that observed in so-called absent pulmonary valve syndrome.²¹ Further distally, aortic coarctation is common, occurring in more than four-fifths of patients. The obstructive shelf is typically in preductal location (Fig. 29-9) but can be found paraductally (Fig. 29-10). Ductal tissue is not only incorporated into the stenosing shelf, but also

Figure 29-9 In this heart from a patient with hypoplastic left heart syndrome, the tissue of the arterial duct surrounds the orifice of the isthmus of the aortic arch, producing a preductal coarctation.

Figure 29-10 In this heart, again from a patient with hypoplastic left heart syndrome, the coarctation shelf is in paraductal position, with direct flow possible from the duct into the aortic isthmus.

may extend proximally and distally,²² an important point for those undertaking surgical palliation of these patients.

The Coronary Arteries and Conduction Tissues

Abnormalities of the coronary arteries, such as ventriculo-coronary fistulas and abnormal tortuosity, are more common in the subgroup of patients with mitral stenosis and

aortic atresia, but not nearly as frequent as in pulmonary atresia with intact ventricular septum (see Chapter 30). Coronary arterial fistulas, if present, are not necessarily associated with abnormalities of the right ventricular myocardium, but can produce an increased risk of mortality at the first stage of Norwood reconstruction.²³ The conduction tissues are in their expected location, albeit with miniaturisation of the left bundle branch in keeping with the size of the left ventricle.

NATURAL HISTORY

The two most significant advances in altering the natural history in infants with hypoplasia of the left heart are the widespread availability of antenatal ultrasonography and prostaglandin E_1 . As mentioned above, in the current era the majority of neonates who survive to term have already been diagnosed antenatally by ultrasonography. It is increasingly rare for neonates to present with critical congenital cardiac disease with shock, acidosis, and hypoxemia.²⁴ Antenatal diagnosis allows the neonate to be delivered at or near a tertiary care centre for therapy, stabilisation with prostaglandin, and the ability to plan intervention on a semi-elective basis, with a decreased likelihood of cerebral injury, as well as hepatic, renal, or cardiac dysfunction. Prior to the availability of prostaglandin E_1 , virtually all children died in early infancy, nine-tenths within the first 30 days of life.²⁵

Atresia, or significant hypoplasia, of the mitral valve results in a physiological state where there is complete mixing of the systemic and pulmonary venous circulations in the right atrium. The mixed venous blood then passes across the tricuspid valve to the dominant right ventricle. Thereafter, the right ventricular output must be divided between the pulmonary and systemic arterial circuits, which are in parallel. In this situation the saturations of oxygen in the pulmonary artery and the aorta are equal, and the ventricular output is the sum of the flow of blood to the lungs and to the systemic circulation. The proportion of the ventricular output that goes to either of these vascular beds is determined by the relative resistance to flow into the two circuits. Tricuspid regurgitation may further add to the volume work of the dominant right ventricle.

THE TRANSITIONAL CIRCULATION

In the neonate with hypoplasia of the left heart, the normal fall in pulmonary vascular resistance over the first few hours to days of life, in the absence of a significant obstruction to flow into the lungs, results gradually in increased pulmonary flow. The right ventricle becomes progressively volume overloaded, with mildly elevated end-diastolic and atrial pressures. Expected physiological responses include oliguria, with an increase in retention of salt and water, an increase in ventricular stroke volume, tachycardia, and tachypnea. If the saturation of oxygen in the pulmonary veins is assumed to be from 95% to 100%, and that in the systemic veins is between 60% and 65%, with equal distributions of pulmonary and systemic flows, and hence venous returns, the saturation of oxygen in the aorta will be approximately 80%. This has been termed the so-called balanced circulation.

With a continued decrease in the pulmonary vascular resistance, there is an increase in flow to the lungs, and the neonate may show signs of respiratory distress. The greater proportion of pulmonary venous return in the mixed ventricular blood results in an elevated saturation of oxygen in the systemic circulation, to approximately 90% or higher, and visible cyanosis may be mild or absent. Prior to surgical intervention, a number of manoeuvres may be employed to balance the circulation, in attempts to maximise delivery of oxygen and systemic flow. These include sedation, neuromuscular blockade, tracheal intubation and mechanical ventilation with precise control of pH and alveolar pressures of carbon dioxide, addition of inspired gases such as nitrogen or carbon dioxide, and transfusion to increase the viscosity of the blood. Manoeuvres that lower systemic vascular resistance, such as the use of intravenous vasodilators, despite reducing pulmonary flow, may compromise systemic flow. The goal of management prior to surgery, therefore, should not be to seek to balance the circulations by equalizing pulmonary and systemic flows, but rather to provide adequate delivery of oxygen to the tissues. In usual practise, this correlates more or less with equal pulmonary and systemic flows. Many patients, nonetheless, will have adequate delivery of oxygen with minimal symptoms despite significantly increased flow to the lungs, a situation frequently dubbed pulmonary over-circulation. Such pulmonary over-circulation, nonetheless, does not cause a problem unless accompanied by systemic undercirculation. In practise, most patients tolerate the transitional circulation well for a number of days or longer, and most invasive interventions can and should be avoided. In most of these patients, an escalation in ventilation and pharmacological management only temporises the need for surgical intervention, and increases the potential for iatrogenic complications. Patients with unbalanced functionally univentricular physiology may be considered in a spectrum of two physiological extremes, namely, inadequate flow to the lungs, which results in hypoxemia, and excessive flow, which results in congestive cardiac failure.

Inadequate Flow

The newborn with hypoplasia of the left heart and an inadequate arterial saturation of oxygen, below 65%, may have limited flow of blood to the lungs due to elevated pulmonary vascular resistance. More commonly, however, the cause is obstruction to pulmonary venous outflow, most commonly due to a restrictive intra-atrial communication. Alternatively, the hypoxaemic newborn may have adequate flow to the lungs, but this will be hypoxaemia due to pulmonary disease, the latter causing intrapulmonary right-to-left shunting.

Excessive Flow

A more common situation in patients with hypoplasia of the left heart who have not undergone surgical intervention is progressively increasing flow to the lungs at the expense of systemic flow. When severe, this results in systemic hypoperfusion, metabolic acidosis, and shock. Once persistent patency of the arterial duct has been confirmed, manoeuvres should be instituted to minimise systemic and maximise pulmonary vascular resistance. Hypotensive patients

with a relatively high arterial oxygen saturation, greater than 95%, generally have a severe steal by the pulmonary vascular circuit from the combined ventricular output. In these over-circulated patients, excessive inotropic support, particularly at alpha-doses, should be minimised. Reduction of afterload using agents such as sodium nitroprusside or milrinone may be especially helpful in patients with elevated systemic vascular resistance and an adequate blood pressure.

Patients with hypoplasia of the left heart and high arterial saturations, nonetheless, may suffer decreased delivery of oxygen to the tissues. The increased content of oxygen comes at the expense of a relative reduction of systemic flow, which results in inadequate perfusion, metabolic acidosis, and low cardiac output. In addition, ventricular mural tension and consumption of oxygen are increased in the dilated, volume-overloaded, dominant right ventricle, potentially contributing to myocardial dysfunction and atrioventricular valvar regurgitation. Progressive metabolic acidosis is a worrisome sign in these patients and requires prompt evaluation and, in many cases, surgical intervention.

Manoeuvres to increase pulmonary vascular resistance have been shown clinically to be effective in reducing excessive flow to the lungs. Provision of supplemental inspired nitrogen or carbon dioxide may elevate pulmonary vascular resistance by inducing alveolar hypoxia. The haematocrit should be maintained at greater than 40% to 45%, as the increased viscosity may also serve to elevate the pulmonary vascular resistance. Intubation and mechanical ventilation with sedation, paralysis, and permissive hypoventilation can be used to elevate the partial pressures of carbon dioxide into the range from 40 to 50 torr.

As already discussed, patients with marked over-circulation and systemic hypoperfusion should not undergo a lengthy period of medical management of their unstable physiology prior to surgical intervention. If a patient requires intubation and sedation to maintain adequate systemic flow, early surgical intervention is indicated to achieve more favourable physiology.

CLINICAL PRESENTATION AND PRE-OPERATIVE STABILISATION

Neonates tend to present in one of three mutually exclusive ways. If the diagnosis has been made prenatally, an expectant team of caregivers manages a metabolically stable neonate. Neonates can also present with symptoms of mild congestive heart failure, with or without a cardiac murmur and no dysfunction of the end-organs, or with profound circulatory collapse and failure of organs in multiple systems. In this last group, a sudden deterioration takes place, with rapidly progressive congestive cardiac failure and shock occurring concurrent with constriction of the arterial duct. There is decreased systemic perfusion, and greatly increased flow to the lungs, largely independent of the level of pulmonary vascular resistance. The peripheral pulses are weak to absent. Renal, hepatic, coronary, and central nervous system perfusions are compromised, possibly resulting in acute tubular necrosis, necrotizing enterocolitis, or cerebral infarction or haemorrhage. A vicious cycle may also result from inadequate retrograde perfusion of the ascending aorta and coronary arterial supply, with further myocardial dysfunction and continued compromise of

flow to the coronary arteries. The ratio of pulmonary-to-systemic flows approaches infinity as systemic flow nears zero. Thus, one has the paradoxical presentation of a profound metabolic acidosis in the face of a relatively high partial pressure of oxygen, in the region of 70 to 100 mm Hg. At the initial presentation, sepsis is frequently suspected before the cardiac diagnosis is made.

Analysis of arterial blood gases is typically a commonly employed indicator of haemodynamic stability and adequacy of systemic delivery of oxygen. While a low arterial saturation of oxygen, in the region from 75% to 80%, with a normal pH and partial pressures of carbon dioxide, indicates an acceptable balance of systemic and pulmonary flows with adequate peripheral perfusion, elevated saturations of greater than 95%, when associated with acidosis, represent significantly increased pulmonary and decreased systemic flows, with probable myocardial dysfunction and secondary effects on other organ systems.

Oxygen

In general, supplemental oxygen should be avoided pre-operatively in the infant with hypoplasia of the left heart. Oxygen will act as a pulmonary vasodilator, increasing the flow of blood to the lungs at the expense of systemic flow. The presence of pulmonary pathology, such as atelectasis, meconium aspiration, or pneumonia, or a restrictive interatrial communication, may result in a requirement for supplemental oxygen. In the absence of these features, most neonates with hypoplasia of the left heart have increased pulmonary flow prior to surgery, with saturations of oxygen in room air from 88% to 95%, representing partial pressures of oxygen from 45 to 50 mm Hg or greater. Patients with a mildly restrictive interatrial communication and/or elevated pulmonary vascular resistance will have saturations of oxygen in the high 70s to low 80s. Although the temptation is to increase the inspired oxygen, if the low saturation represents the best balance between pulmonary and systemic flows, increasing the supplemental oxygen may paradoxically decrease delivery of oxygen to the tissues.

When to Treat a High Saturation of Oxygen

The clinically stable infant may tolerate significantly increased pulmonary flow in the pre-operative period without significant intervention or obvious untoward effects. When the diagnosis is made early, before significant constriction of the arterial duct and development of a state of low flow, acidosis is usually avoided. Infants in this setting often have a mild degree of restriction across the interatrial communication, with left atrial hypertension elevating pulmonary vascular resistance, and limiting to some extent the flow to the lungs. Although tachypnoeic, with respiratory rates from 60 to 80 per minute, and with an arterial oxygen saturation of 90% or higher, they remain clinically stable with minimal intervention. This group of patients maintains adequate systemic flow despite increased pulmonary flow. Further interventions designed to achieve an arbitrary partial pressure of oxygen, such as intubation and/or supplemental provision of inspired gases, may not stabilise the patient, but rather increase the potential for iatrogenic complications. In short, the neonate without significant symptoms of congestive heart failure, acidosis, or progressive respiratory distress should not necessarily require significant therapy to treat high partial pressures of

oxygen. Only two subsets of infants require aggressive pre-operative management of the balance between their pulmonary and systemic blood flow. The first group is made up of those who are diagnosed late, following constriction of the arterial duct and circulatory collapse. The second group is composed of those with clinically significant pulmonary over-circulation and systemic undercirculation, independent of the timing of diagnosis.

Presentation in Shock

Infants presenting with inadequate systemic cardiac output, either due to ductal constriction or pulmonary over-circulation, often have depressed cardiac function with significant tricuspid insufficiency, profound metabolic acidosis, usually some hepatic and renal failure, and occasionally bowel ischaemia or disseminated intravascular coagulopathy. These infants require rapid and aggressive resuscitation. Prostaglandin E_1 must be given, the dose being adjusted according to the degree of patency of the arterial duct as revealed echocardiographically. Intravenous infusions of catecholamines, such as dopamine or adrenaline, will help augment overall cardiac output. Sedation, paralysis, and endotracheal intubation will allow for controlled ventilation and minimise systemic consumption of oxygen. If a patient continues to have inadequate delivery of systemic oxygen despite controlled ventilation with 21% oxygen, the addition of inspired carbon dioxide has been shown to improve systemic delivery of oxygen (see below). Most commonly, infants with hypoplasia of the left heart presenting in shock benefit from recovery of end-organ function before proceeding to the operating room for surgical reconstruction or transplantation. Importantly, infants with persistent metabolic acidosis despite resuscitative efforts should be evaluated by echocardiography to establish adequate patency of the arterial duct. Rarely, a pre-operative infant with hypoplasia of the left heart persists with medically refractory pulmonary over-circulation and may require urgent construction of the initial stage of the Norwood sequence.

Hypotension

Although mild pre-operative hypotension is common, and frequently thought to be caused by increased pulmonary flow at the expense of systemic flow, alternative aetiologies also play a role. Prostaglandins are potent pulmonary and systemic vasodilators, and adequate fluids are needed following their administration. Neonatal myocardium is particularly sensitive to intracellular calcium and glucose, so the levels of both agents in the serum should be monitored periodically. Myocardial dysfunction may co-exist, and although small-to-moderate doses of inotropic agents are frequently beneficial, large doses may have a deleterious effect, depending on the relative effects on the systemic and pulmonary vascular circulations. Preferential selective elevations of systemic vascular tone will secondarily increase pulmonary flow, and careful monitoring of mean arterial blood pressure and arterial saturations of oxygen is warranted. Tricuspid regurgitation from an anatomically abnormal valve, or secondary to ventricular dysfunction, may also contribute. Low doses of inhibitors of phosphodiesterase, such as milrinone, which may seem counter-intuitive for the mildly hypotensive patient, may improve overall perfusion and delivery of oxygen. Patients with hypotension that remains refractory despite all of the above interventions should undergo echocardiographic evaluation to ensure that the arterial duct remains widely patent and non-restrictive.

Inadvertent or unrecognised problems in the administration of prostaglandin E_1 can constrict the arterial duct.

Inspired Gases

The use of mixtures of inspired gases to balance the pulmonary and systemic flows prior to surgical intervention remains controversial.^{26–28} Until recently, prospective, controlled data comparing hypoxia to hypercarbia was limited to studies in shunt-dependent animal models of the functionally univentricular circulation.²⁹ Use of both induced alveolar hypoxia and increased inspired carbon dioxide produced a significant decrease in the ratio of pulmonary to systemic flows compared to baseline. In a prospective crossover study measuring saturations of oxygen in the superior caval vein and aorta while estimating saturations of oxygen in the brain using near infrared spectroscopy, however, it was shown that hypoxia induced by nitrogen and hypercarbia by carbon dioxide both decreased the ratio of pulmonary to systemic flows. Importantly, only hypercarbia increased cardiac output and cerebral oxygenation.²⁷

In our practise at The Children's Hospital of Philadelphia, therefore, we tend not to use inspired gases pre-operatively. Surgery is undertaken as soon as is medically and logistically possible. For the neonate presenting with circulatory collapse and pulmonary over-circulation, and already intubated and mechanically ventilated, nonetheless, we give inspired carbon dioxide until surgery is undertaken. For patients in whom surgery must be delayed, and there is clinically significant pulmonary over-circulation with low systemic flow, nitrogen is inspired to the spontaneously breathing patient, and carbon dioxide reserved for the mechanically ventilated patient until surgery is undertaken.

Restrictive Atrial Septum

A severely restrictive atrial septum limits outflow from the pulmonary veins. If coupled with mitral atresia, this results in profound obstruction to left atrial egress, producing pulmonary venous hypertension and hypoxaemia following birth. Newborns with this combination are extremely unstable, and difficult to manage immediately following birth. Recent strategies to improve the dismal prognosis have been met with limited, albeit encouraging, success, including prenatal intervention with static atrial septal dilation with or without placement of a stent, and/or planned delivery by cesarean section at a centre equipped to provide surgical or catheter intervention within a very short time frame. Following birth, if inadequate flow to the lungs and systemic oxygenation are confirmed, the infant should be intubated, umbilical access obtained, and prostaglandin E_1 given in the delivery room, followed by direct transportation to the operating room or catheterisation lab where the planned septectomy or catheter intervention may be performed. In the absence of a prenatal diagnosis, the clinical presentation is identical to obstructed totally anomalous pulmonary venous return, or severe pulmonary disease. From the stance of management, intubation, positive end expiratory pressure, and supplemental oxygen are needed to maintain a saturation of oxygen in the aorta of around 80%, coupled with umbilical access, inotropic support, and other supportive strategies.

Unfortunately, the association of a severely restrictive or intact atrial septum with hypoplasia of the left heart has a

significantly worse prognosis over the short and long term compared with other forms of left heart hypoplasia^{30,31} mainly due to the secondary changes that occur in the pulmonary vascular bed from fetal obstruction to pulmonary venous outflow (see Fig. 29-5). The pulmonary vascular tree is abnormal in all patients with hypoplasia of the left heart, with an increase in the number of arteries per unit area of lung, the arteries themselves having a considerable increase in muscularity. Increased medial arterial thickness is present, as well as extension of muscle into smaller and more peripheral arteries than is normal. This may explain the predilection towards extreme sensitivity of the pulmonary vascular bed to vasoactive agents. The pulmonary veins are typically dilated with thickened walls. The degree of restriction at the atrial level influences the pathological findings within the pulmonary vascular tree. Increased arterial tortuosity and arteriopathy have been noted, along with arterialisation of the pulmonary veins.³⁰ These pulmonary venous abnormalities further contribute to the pathophysiology once these infants are born, and may explain why most continue to do poorly with high mortality despite creation of a large and effective interatrial communication at birth.

PRE-OPERATIVE EVALUATION

Newborns with hypoplasia of the left heart require a thorough evaluation of cardiac and non-cardiac issues upon admission to the intensive care unit. Vascular access should be secured, prostaglandin administered, and evaluation of acid-base status undertaken. The physical examination should assess adequacy of systemic perfusion, and carefully evaluate for additional congenital anomalies and dysmorphic features. A complete echocardiogram is usually sufficient to plan surgical intervention. In particular, care should be taken to establish the presence or absence of bilateral superior caval veins; the number of, and patterns of flow in, the pulmonary veins; the state of the atrial septum and ventricular myocardium; the anatomy and function of the tricuspid and pulmonary valves; the size of the ascending aorta; and the presence of any abnormal patterns of branching of the brachiocephalic arteries. Representative examples of important aspects of the anatomy are shown in Figures 29-11 to 29-13. The patency and characteristics of flow through the arterial duct are crucial to maintaining the stability of the patient and understanding the physiology, and may be utilised to estimate the ratio of pulmonary to systemic flows³² (Fig. 29-14). Coronary arterial sinusoids may be identified in some patients in the setting of aortic atresia and mitral stenosis. These are particularly important to identify as they have been recently shown to be risk factors for mortality following surgical intervention.^{33,34} Should there be evidence of retardation of growth or additional congenital anomalies, the remaining systems such as the brain, kidneys, liver, and gastrointestinal tract should be evaluated. Consultation with a clinical geneticist may be helpful.

THERAPEUTIC OPTIONS AND POST-OPERATIVE CARE

There are currently four options available for the neonate with hypoplasia of the left heart. The first is to abstain from intervention. The second alternative is that of

Figure 29-11 These subcostal echocardiographic images show the atrial septum, and the right and left atria. In panel A, there is a defect of adequate size in the atrial septum, allowing pulmonary venous egress to the right atrium, right ventricle, and systemic circulation. Panel B shows a thickened and intact atrial septum. The patient from whom the image in panel A was obtained was asymptomatic, with an acceptable saturation of oxygen. The patient from whom we obtained the image shown in panel B was profoundly ill, hypoxaemic, and required mechanical ventilation, with urgent placement of a stent in the atrial septum, as shown in panel C. Placement of the stent produced marked improvement in oxygenation. (Courtesy of Dr Michael Quartermain, Children's Hospital of Philadelphia.)

staged reconstruction, beginning with the first stage of the Norwood protocol and culminating in construction of the Fontan circulation. The third option is to opt for primary cardiac transplantation. The fourth involves a hybrid approach, stenting the arterial duct, banding the pulmonary arteries, and opening the interatrial communication if necessary.

The option of declining to intervene is now controversial.^{26,35,36} Most centres currently active in cardiac surgery for neonates and infants do not actively offer non-intervention,²⁶ although non-intervention might be adopted by many providers of health care if personally faced

with the situation.³⁵ It is beyond the scope of this chapter to review the ethical issues, tenets of informed consent, and changing landscape of this controversial topic.

EVOLUTION OF SURGICAL THERAPY

Surgical palliation for a patient with hypoplasia of the left heart was first attempted in 1961,³⁷ and the first survivors were reported in the early 1970s.^{38,39} Alternative innovative approaches were then reported in the later part of the 1970s, indicating that staged reconstruction would be needed successfully to achieve the Fontan circulation.⁴⁰

Figure 29-12 The apical echocardiographic image of a newborn shows the typical findings of hypoplasia of the left heart, in this instance produced by mitral stenosis and aortic atresia. Note the diminutive cavity of the hypoplastic left ventricle, with hypertrophy of the left ventricular myocardium (double-headed arrow) when compared to the normal thickness of the right ventricular wall. (Courtesy of Dr Michael Quartermain, Children Hospital of Philadelphia, Philadelphia, Pennsylvania.)

Such a staged approach was formulated by Norwood during the early 1980s.⁴¹ Even in experienced centres, however, initial survival remained poor. Shortly thereafter, primary cardiac transplantation was shown to be achievable in the neonate.⁴² While the initial surgical mortality was superior to staged reconstruction, and the possibility of a biventricular circulation was appealing, the approach was limited by the availability of suitable donors, with many patients dying in the waiting period prior to transplantation. The introduction of ABO-incompatible cardiac transplantation increased the availability of donors,⁴³ albeit that such an approach has not universally been adopted as primary

therapy at many centres.²⁶ The most recent major innovations have involved combined transcatheter and surgical approaches.^{44,45} Such palliation with a ductal stenting and banding of the pulmonary arteries was initially conceived as a bridge to cardiac transplantation, but more recently has been used prior to a simultaneous reconstruction of the aortic arch and construction of a superior cavopulmonary connection, dubbed the comprehensive second stage. The ideal surgical strategy, therefore, remains controversial. Most likely it will eventually be tailored to fit the risk factors of the specific patient. Results from all currently available strategies, nonetheless, have vastly improved the outlook for infants born with hypoplasia of the left heart.

FIRST STAGE OF RECONSTRUCTION

There are three main principles underscoring the first stage of palliation. First, it is essential to establish an unobstructed intra-atrial communication, providing unobstructed pulmonary venous inflow. The second requirement is unobstructed systemic outflow, while the third is to provide a reliable source of flow of blood to the lungs, allowing development of the pulmonary vasculature as well as reducing the volume load on the ventricle. Nearly all children with hypoplastic left heart syndrome are candidates for surgery. The first stage of palliation, nonetheless, carries considerable risk, and parents should be counselled appropriately. Chromosomal abnormalities or extracardiac malformations are frequently associated with higher risk, and may be considered to represent relative contraindications, depending on their severity. Patients with severe tricuspid valvar regurgitation or right ventricular dysfunction also have an increased risk of mortality.

The first stage of reconstruction using the classic Norwood operation is typically performed through a median sternotomy, and involves construction of a modified Blalock-Taussig shunt. Recently, there has been interest in creation of the shunt from the right ventricular infundibulum to the central pulmonary arteries.⁴⁶ The theoretical advantages of a shunt from the right ventricle to the pulmonary arteries

Figure 29-13 Panel A shows an intra-operative image following sternotomy in a patient with aortic atresia. Note the diminutive ascending aorta, which measured 2 millimeters, compared to the pulmonary trunk. The angiographic image shown in panel B is from a different patient with aortic atresia. Note the filling of the arteries to the head and neck through the arterial duct, with continuation of retrograde flow to fill the diminutive ascending aorta and the coronary arteries.

Figure 29-14 The Doppler spectral display shows the waveforms generated when sampling in the descending aorta after first stage of reconstruction for hypoplasia of the left heart. Flow below the baseline represents antegrade flow in systole; flow above the baseline represents retrograde flow in diastole. A ratio is calculated by measuring the velocity-time integral of retrograde and antegrade flow done by using planimetrics for the area under each curve and dividing the former by the latter. Three patients are exhibited. The top panel demonstrates a small amount of flow reversal, indicating relatively low amounts of flow to the pulmonary artery; the middle panel demonstrates a moderate amount of flow reversal into the pulmonary artery; and the lower panel demonstrates a large degree of reversal, indicating a large amount of flow into the pulmonary artery in a retrograde fashion from the descending aorta. (Reproduced with permission from Rychik J, Bush DM, Spray TL, et al: Assessment of pulmonary/systemic blood flow ratio after first-stage palliation for hypoplastic left heart syndrome: Development of a new index with the use of Doppler echocardiography. *J Thorac Cardiovasc Surg* 2000;120:83.)

are a higher post-operative diastolic pressure,⁴⁷ improved coronary arterial flow, pulsatile end-organ perfusion, and improved growth of the central pulmonary arteries.⁴⁸ This technical modification, however, employs a small incision in the systemic right ventricle, and the long-term effects on ventricular function and/or arrhythmia are unknown. Follow-up studies examining the theoretical advantages of the suggested modification are currently under way, but short term in duration. Decades of follow-up are likely to be necessary to determine the better overall surgical strategy to be used in the neonatal period.

The technical aspects of the operation vary among centres, and controversy exists regarding the best strategy for intra-operative support, especially with regard to that given during reconstruction of the aortic arch (see Chapter 13). At the Children's Hospital of Philadelphia, and other centres, circulatory arrest is used. The arterial duct is ligated on the side of the pulmonary artery and divided on the aortic side. The atrial septum is completely excised, and the pulmonary trunk divided close to its bifurcation, the resulting defect being closed with a patch of homograft tissue. At a point beginning immediately adjacent to

the divided trunk, the diminutive aorta is incised inferiorly along the transverse arch through the site of ductal insertion. All redundant ductal tissue is excised, and the ascending aorta is anastomosed to the pulmonary trunk, the aortic arch being reconstructed using a homograft patch. The distal end of the Blalock-Taussig shunt is then connected to the right pulmonary artery, or else the shunt is placed from the right ventricle, thus completing the palliative procedures.

The surgical results of the first stage of reconstruction have progressively improved after the initial successes reported in the early 1980s.⁴¹ In the current era, it is increasingly recognised that there are patients having standard as opposed to higher risk for the first stage of palliation. Those with increased risk have the need for mechanical ventilation prior to surgery, low weight at birth, typically less than 2.5 kg, and the association of other cardiac or associated genetic anomalies.^{49,50} Up to 1 in 10 patients with the standard risk have a chance of dying after surgery, whereas those with additional risk factors have an incrementally increased risk.⁴⁹ There is then another risk of up to 1 in 10 patients dying prior to the second stage of palliation,⁵¹ albeit that recent success with home monitoring programmes may reduce this risk.⁵² The expected operative mortality risks for the second stage, involving construction of a superior cavopulmonary connection (Fig. 29-15), and subsequent completion of the Fontan circuit, are currently in the range of no more than 1% to 2%. Thus, the greatest risk of death for newborns with hypoplastic left heart syndrome undergoing surgical reconstruction is concentrated

Figure 29-15 The cartoon shows the second stage of the Norwood sequence of palliative surgery for hypoplasia of the left heart. The outflow tract from the right ventricle has been reconstructed to supply the systemic circulation, while a superior cavopulmonary anastomosis supplies systemic venous blood to the lungs.

in the periods of neonatal and early infant life through the second stage of palliation.

INFANT CARDIAC TRANSPLANTATION

In recent years, survival following cardiac transplantation in the neonate has improved, and this remains an important surgical option for patients with acquired and congenital cardiac disease in whom medical and surgical treatment schemes are exhausted.⁵³ In neonates, hypoplastic left heart syndrome remains the most common indication for transplantation, either as initial therapy or as a treatment for those failing attempted staged reconstruction. The overall survival for cardiac transplantation in children worldwide is 73% at 1 year, and 70% at 4 years after transplantation.⁵⁴ The biggest drawback to the routine use of transplantation as primary therapy for neonates with hypoplastic left heart syndrome remains the lack of available organs. Even with most centres in North America performing staged reconstruction as primary therapy, thus limiting the number of babies with hypoplastic left heart syndrome waiting for an organ at any given time, up to one-third of listed children never receive a transplant because of the limited supply of organs. Risk factors for early mortality after transplantation in children, for any underlying cause, include congenital cardiac disease, use of a ventricular assist device prior to transplantation, younger age, presence in an intensive care unit, retransplantation, and transplantation in centres with low volume. The surgical technique is conceptually straightforward, with the primary technical consideration being reconstruction of the aortic arch. The procedure is more technically demanding if staged reconstruction has already been performed. Because of the need to reconstruct the aortic arch, residual coarctation or stenosis can develop at the anastomotic site, and may be successfully treated with balloon angioplasty. Rejection of the graft can occur at anytime, and up to three-quarters of children will have at least one episode of rejection. Infectious complications are common, occurring most often in the immediate period after transplantation. They are a major cause of early morbidity and mortality, especially in the first year after transplantation. Longer-term sequels include lymphoproliferative disease and graft vasculopathy, both affecting up to one-tenth of recipients.

TRANSPLANTATION VERSUS STAGED RECONSTRUCTION

As already discussed, there is no consensus concerning the optimal surgical management of hypoplastic left heart syndrome. At the present time, the overall risks of death are similar presuming the availability of organs continues at the current rate, and there is no significant shift in the numbers of centres adopting one or another strategy. If transplantation were to be performed on the basis of intention to treat at more centres, and the supply of donors did not change, the rate of death prior to transplantation would inevitably increase. Primary transplantation, therefore, is not a reasonable strategy for all patients. Thus, the optimal strategy depends upon the long-term risks of dying, and the morbidity associated with each strategy. Organs should be allocated to those patients for whom no reasonable reconstructive strategy exists. These include patients with a poorly functioning right ventricle with severe tricuspid

regurgitation. Patients who have failed the first stage of reconstructive palliation despite optimal medical management should also be considered for transplantation. There are certain morbidities inherent in transplantation, such as immunosuppression, lymphoproliferative disease, and graft vasculopathy, and others inherent in staged reconstruction culminating in construction of the Fontan operation circuit, such as arrhythmias, protein-losing enteropathy, and thromboembolism. There are also a number of morbidities that are nearly identical with either strategy, including retardation of growth, limitation of exercise, need for chronic medication, developmental delay, and psychological factors produced by a chronic disease. Further research is necessary, therefore, to determine which strategy is ideal for individual patients and their families.⁵⁴

COMBINED SURGICAL AND TRANSCATHETER, OR HYBRID, PALLIATION

The combined transcatheter and surgical approach was pioneered by Schranz and colleagues in Geissen, Germany.⁴⁴ Initially, palliation with a ductal stent and banding of the pulmonary arteries was conceived as a bridge to cardiac transplantation. More recently, the approach has evolved with the collaborative modifications of Galantowicz and Cheatham in Columbus, Ohio, with modifications of the Geissen technique performed prior to a planned comprehensive second stage, involving surgical reconstruction of the aortic arch combined with a superior cavopulmonary connection. Initial palliation is performed by intraoperative, off-pump, placement of bands on both pulmonary arteries, followed by a stent in the arterial duct placed through a sheath in the pulmonary trunk (Fig. 29-16). Alternatively, the entire palliative procedure may be performed with transvascular catheterisation, with placement of a stent in the arterial duct and flow-restricting devices in the proximal portions of the right and left pulmonary arteries. When necessary, transcatheter enlargement of an atrial septal defect is performed as a separate procedure. Occasionally, a stent is placed within the oval fossa to create a durable interatrial communication (Fig. 29-17). At the age of 3 to 6 months, a comprehensive second stage, incorporating the elements of the traditional first and second stages, is performed, with a plan to complete the Fontan circulation using transcatheter techniques. During the comprehensive second stage, the bands on the pulmonary arteries and the ductal stent are removed, the pulmonary arteries are repaired, the aorta is enlarged and anastomosed to the pulmonary trunk as in the traditional first stage of palliation in the Norwood sequence, atrial septectomy is performed with removal of any atrial stent, and the operation is completed by construction of a modified hemi-Fontan connection. This modification includes anastomosing the transected distal end of the superior caval vein in an open fashion to the right pulmonary artery, and then excluding it with a pericardial patch within the right atrium. This provides a rim of tissue below the right pulmonary artery to anchor an eventual stent placed during transcatheter completion of the Fontan circulation. In addition, a ring cut from a Gore-Tex tube graft attached to a radio-opaque marker is placed around the inferior caval vein between the diaphragm and right atrium to facilitate

Figure 29-16 The cartoon shows the initial steps of the hybrid procedure for hypoplastic left heart syndrome. Bands are placed surgically round the right and left pulmonary arteries, and a stent is placed in the arterial duct.

Figure 29-17 The cartoon shows the conclusion of the hybrid palliative strategy for hypoplasia of the left heart. The stent in the arterial duct provides unobstructed flow to the distal aorta, and the bands placed on the right and left pulmonary arteries restrict the flow of blood to the lungs. A catheter-based atrial septectomy is augmented by implantation of a stent across the atrial septum, assuring adequate egress of pulmonary venous blood to the right atrium.

precise placement, and to serve as an anchor for the inferior margin of the stent. At approximately 2 years of age, the Fontan circulation is completed by placement of a covered stent. With this strategy, there is but one exposure to cardiopulmonary bypass, aortic cross-clamping, and circulatory arrest, although there is a significant learning curve. Although promising, it is not yet clear whether this hybrid strategy will yield better outcomes over the long term.⁴⁵

ROUTINE ACUTE POST-OPERATIVE MANAGEMENT

Post-operative Management in the Operating Room

Post-operative management begins in the operating room with separation from cardiopulmonary bypass. Most of the monitoring techniques that we employ in the post-operative period are initiated in the operating room, either at the outset or completion of surgery. We prefer to place umbilical arterial and venous catheters pre-operatively, and to maintain patients with spontaneous ventilation prior to surgery. An indwelling catheter is inserted into the urinary bladder, and a peripheral arterial catheter is inserted if an umbilical arterial catheter is not in place.

Following a loading dose of milrinone while on cardiopulmonary bypass, modified ultrafiltration is then performed to achieve haemoconcentration and reduction of total body water, following which the patient is separated from extracorporeal circulation. Upon decannulation, two or three transthoracic right atrial catheters are placed through the right atrial appendage. Inotropic support is initiated and the patient is weaned from cardiopulmonary support, with adjustment of inotropic support as necessary. Mechanical ventilatory support is then resumed. Prior to closure of the sternum and the median sternotomy, temporary epicardial atrial and ventricular pacing wires are placed. In selected patients with excessive myocardial oedema, cardiopulmonary instability, or mediastinal bleeding, or in rare cases in which post-operative mechanical circulatory support is required, the chest can be left open, with a patch of silicone elastomer sutured to the skin for coverage of the incision.^{55,56} With our current protocol, this is performed in approximately one-twentieth of patients. After haemodynamic stabilisation and closure of the chest, the patient is transported to the intensive care unit.

Acute Post-operative Management in the Intensive Care Unit

Early post-operative management following the first stage of palliation is based on the pathophysiological conditions typically present (Table 29-1).

Cardiovascular Pathophysiology in the Early Post-operative Period

The most important physiological consideration after the first stage of palliative reconstruction is maximizing the ratio of delivery to extraction of oxygen. This is fundamentally a function of systemic requirement for oxygen, systemic blood flow, and the systemic arterial content of oxygen, which depends on the haematocrit and the percent of oxyhaemoglobin (Fig. 29-18). In the patient with circulation in series, the items listed above are essentially the sole variables determining effective delivery of oxygen. In patients with a functionally univentricular circulation, in

TABLE 29-1

EARLY MANAGEMENT AFTER THE FIRST STAGE OF RECONSTRUCTION

Optimize cardiac output

contrast, the parallel delivery of pulmonary to systemic flows, as well as the regurgitant fraction, are potentially confounding variables in optimizing effective delivery. In the post-operative patient with a systemic-to-pulmonary arterial shunt, the ratio of flows is particularly important. In keeping with the potential significance of this variable, there have been several theoretical and clinical studies aimed at determining the ideal ratio.⁵⁷⁻⁶¹ Although some mathematical studies have predicted that optimal availability will occur with a ratio of less than 1,⁵⁸ models that incorporate the non-linear function of extractability,⁶⁰ as well as more complex computational methods⁵⁷ and animal studies,⁶¹ suggest that optimal delivery occurs at a ratio of approximately 1. Calculation of this ratio, however, is an estimate at best, as there is no truly mixed venous blood, the pulmonary venous saturation is frequently estimated,^{32,62} and the possibility of a significant regurgitant fraction across the tricuspid valve is frequently overlooked.

Historically, the ratio of flows has been a vexing and frequently critical variable after the initial stage of palliative reconstruction. Regarding the regulation of pulmonary flow, the resistance provided by the systemic-to-pulmonary arterial shunt, which is directly proportional to its length and inversely proportional to its radius to the fourth power, is perhaps the most important of the variables that can be controlled. In the physiological range of cardiac output, manipulation of the diameter, length, and location of the shunt has a substantially greater impact on pulmonary flow than does pharmacological or ventilatory manipulation of intrinsic pulmonary vascular resistance. While changes in intrinsic resistance will still have an effect on pulmonary

flow even in patients with a small shunt, the magnitude of the change in pulmonary flow is almost negligible in comparison with that affected by changing the size of the systemic-to-pulmonary arterial shunt and the systemic vascular resistance.⁵⁷ Thus, while the ratio of flows can be a useful means of monitoring and understanding the circulatory and metabolic conditions in patients who have undergone the first stage of reconstruction, moderate changes in pulmonary resistance are of minor practical importance when a shunt of appropriate size is used.

With the routine application of an intermediate palliation prior to completion of the modified Fontan circulation, such as construction of the hemi-Fontan procedure or a bidirectional superior cavopulmonary connection at approximately 4 to 6 months of age, it is no longer important to place a shunt of adequate size to accommodate pulmonary flow sufficient for an older infant. Accordingly, at Children's Hospital of Philadelphia and many other centres, the shunt typically has a diameter from 3.5 to 4 mm if arising from the brachiocephalic artery, and 5 mm if arising from the right ventricle. A shunt of this size provides sufficient resistance to flow to prevent pulmonary steal in the early post-operative period, but also allows adequate flow to maintain acceptable systemic arterial oxygenation for up to 6 months of age, when the next stage of palliation is typically performed. Moreover, with the shunt taking origin from the base of the right subclavian artery, which is typically smaller in diameter than a 3.5-mm shunt,⁶³ pulmonary flow is further limited in the neonate, and will be able to increase to a modest extent with growth of the subclavian artery. Thus, when a shunt of appropriate size is used to provide flow to the lungs, increased pulmonary at the expense of systemic flow becomes a minor variable in managing systemic delivery of oxygen.

In the majority of cases, total cardiac output and systemic extraction of oxygen are the most important, most variable, and most manageable determinants of systemic delivery of oxygen in the acute post-operative period following the initial stage of reconstruction. Importantly, the systemic resistance, ratio of flows, and consumption of oxygen may be more easily manipulated than pulmonary resistance. The typical haemodynamic profile following cardiac surgery with cardiopulmonary bypass in neonates and infants has been well characterised,⁶⁴ with a general pattern, with a decrease in cardiac output reflected by a widening difference in systemic arterial and venous oxygen saturations, demonstrated in multiple

Figure 29-18 Factors causing arterial hypoxaemia may be divided into three main categories: those that reduce the saturation of oxygen in the pulmonary venous blood, those that reduce the saturation of oxygen in the systemic venous blood, and those that reduce the amount of blood flow to the lungs. (Modified from Wernovsky G, McElhinney D, Tabbutt S: Stage I postoperative management. In Rychik J, Wernovsky G [eds]: *Hypoplastic Left Heart Syndrome*. Boston: Kluwer, 2003.)

studies in the setting of both biventricular and univentricular circulations.^{64–68}

Monitoring and Evaluation in the Acute Post-operative Period

Haemodynamic, metabolic, and oximetric monitoring is helpful in the post-operative management after the first stage of palliation (Table 29-2). All patients are monitored with standard functional parameters. Continuous invasive monitoring of systemic venous oxygen saturation is employed at some centres.⁶⁶ While this has been shown to be an effective strategy, it requires placement of a special intracardiac oximetric catheter directly into the superior caval vein. In selected cases, we have found that a transthoracic catheter placed in the superior caval vein under direct vision through the right atrium is useful for assessment of saturations, and avoids the potential complications associated with an additional intravascular catheter. We have a low threshold for performing bedside echocardiography to assess ventricular and valvar function, pericardial effusion, shunt patency, and to estimate the ratio of flows.³² Recently, there has been increased utilisation of non-invasive monitoring of cerebral and somatic oxygen saturations, estimated by near infrared spectroscopy.²⁶ There are on-going studies to assess the specificity and sensitivity of this new monitoring strategy, as well as the impact on perioperative and longer term outcomes.

Management Strategies during the Acute Post-operative Period
Given the expected fall in combined cardiac output, the expected increase in systemic resistance, and the marginal myocardial reserve early after cardiac surgery, it is advantageous both to maximise effective delivery of oxygen to the myocardium and other vital organs, and to minimise myocardial and systemic demand for oxygen. An important means of achieving the latter objective is to prevent excessive and the often inefficient metabolic activity and neurohormonal stress response that typically occur in the acute post-operative period. Neuromuscular blockade and sedation are components of this strategy (see Table 29-2), and should be considered in children with marginal delivery of oxygen.

TABLE 29-2

TYPICAL POSTOPERATIVE PARAMETERS EARLY AFTER THE FIRST STAGE OF RECONSTRUCTION

Continuous Monitoring

Surface electrocardiogram
Pulse oximetry
Central venous pressure
Near infrared spectroscopy (in some centers)

Intermittent Monitoring

Arterial blood gas analysis
Co-oximetry in superior caval vein
Echocardiography

Mechanical Ventilation

Pressure-regulated, volume controlled; ~15 mL/kg
Intermittent mandatory breaths; ~18/min
Positive end-expiratory pressure; ~3–5 mm Hg

Medications

Dopamine and/or adrenaline
Milrinone
Fentanyl

Paralysis interrupts neuromuscular activity that may be induced by the thermoregulatory axis, spontaneous respiratory drive, and agitation, as well as neurovascular stimulation that can directly affect haemodynamic parameters. For sedation, we prefer to use fentanyl, a potent agonist of opioid receptors that also acts to block the stress response that occurs in response to cardiac surgery and endotracheal intubation.⁶⁹ Fentanyl does not induce histamine release or significantly affect systemic or pulmonary haemodynamics.⁶⁹

Full mechanical ventilation removes the burden of respiration from the patient, and accordingly eliminates the metabolic demand that spontaneous respiratory function imposes. We prefer to ventilate paralyzed post-operative patients with the pressure-regulated volume-controlled mode of ventilation (see Table 29-2). Positive end-expiratory pressure has been shown have salutary effects on lung mechanics and pulmonary venous oxygen saturation,^{62,70} and pressures in the range that we use do not have a deleterious impact of effective pulmonary flow.⁶¹ Cardiovascular pharmacotherapy is focused on optimisation of the ratio of delivery and extraction of systemic oxygen, which depends on providing adequate systemic blood flow, adequate but not excessive pulmonary flow, and sufficient oxygen-carrying capacity, as well as minimizing systemic consumption of oxygen (Fig. 29-19). For most levels of consumption of oxygen, systemic delivery is best ensured if the systemic cardiac index is maintained above 2 liters per minute per meter squared. Excessive end-diastolic ventricular volume or pressure increase ventricular wall tension and, hence, myocardial demand for oxygen. Right atrial pressure is thus usually maintained in the range of 6 to 10 mm Hg. Systemic afterload reduction is achieved with milrinone.⁷¹ The other important determinant of cardiac index is heart rate. Bradycardia results in a significant decrease in cardiac output, but tachycardia may result in increased myocardial oxygen consumption without a concomitant increase in cardiac index. The typical target following the first stage of palliation is from 140 to 180 beats per minute. Oxygen-carrying capacity is optimised by keeping the haematocrit in the range of 40% to 50%.

In the early post-operative period, neonates with palliated heart defects have significantly elevated metabolic needs and may be in an energy deficit even prior to surgery. Moreover, cardiac surgery with cardiopulmonary bypass has significant effects on resting energy expenditure and metabolism of nutritional substrate.⁷² Thus, optimisation of nutrition in the early post-operative period is imperative for the facilitation of healing and ensuring the best possible metabolic reserve. Because we tend to initiate enteral nutrition relatively slowly after first-stage palliation, total parenteral nutrition through a central venous catheter, usually the umbilical venous or right atrial catheter, is initiated on the first day after surgery. It is continued until an adequate enteral feeding regime has been established.

Minimisation of Complications in the Intensive Care Unit and Physiological Stress

An important means of optimizing outcome in the greatest number of patients is to avoid intensive care unit complications. We aim to achieve this end by minimizing elective procedures that have the potential for complications, removing invasive catheters, and discontinuing mechanical ventilation and intravenous infusions as expeditiously as is safely possible. Although strategies and interventions such as open sternotomy with delayed sternal

Figure 29-19 Schematic representation of the protean factors affecting delivery of oxygen to the tissues. (Modified from Wernovsky G, McElhinney D, Tabbutt S: Stage I postoperative management. In Rychik J, Wernovsky G [eds]: Hypoplastic Left Heart Syndrome. Boston: Kluwer, 2003.)

closure, peritoneal dialysis, and intracardiac catheters do not frequently cause complications,^{55,56,73,74} we employ them only in selected patients, rather than routinely.

Physiological stress, which can cause increased consumption of oxygen and reactivity of the pulmonary and systemic vascular beds, is minimised as much as possible during the first 12 to 24 hours post-operatively. Suctioning of the endotracheal tube is performed only as necessary, as determined by increased inspiratory pressures, and falling systemic arterial oxygen saturation. Similarly, laboratory tests are drawn from indwelling catheters to avoid the stress of venipuncture, and other potentially painful procedures are avoided if possible.

IDENTIFICATION AND MANAGEMENT OF COMMON PROBLEMS

The most common problems encountered early after the first stage of palliation are low cardiac output and hypoxaemia. While it is not always possible to avoid the development of such problems, rapid recognition and prompt management may have a dramatic effect on outcome when they do occur.⁷⁵

Low Cardiac Output

Low cardiac output is one of the most important predictors of poor outcome after surgery for congenital heart defects.⁷⁶

Patients are at high risk for poor systemic perfusion for a variety of reasons, which can be divided into two principle and overlapping categories, namely, compromised myocardial function, and normal ventricular output but with maldistribution of flow.

Myocardial Dysfunction

Impaired myocardial performance is essentially a universal phenomenon after the first stage of reconstruction. It is due to a combination of factors, some of which are intrinsic to this population, while others are a consequence of cardiac surgery in general. Among the manifold implications of these alterations are increased capillary leakage, perturbation of the normal vasoactive feedback pathways, a systemic inflammatory response, and disturbances in fluid-electrolyte and metabolic homeostasis. As already discussed, combined cardiac output is expected to fall by up to two-fifths during the first night after surgery. A longer duration of cardiopulmonary bypass is known to be a risk factor for low systemic venous oxygen saturation and an increased disparity in systemic arterial and venous oxygen saturations,⁶⁶ and in our experience it has been associated with increased risk of mortality following the first stage of reconstruction.⁷⁷ Cardiac afterload is also affected by changes in systemic resistance which typically occur after cardiopulmonary bypass.⁶⁴ Taken together, these factors may have a substantial impact on myocardial function and ventricular-vascular coupling, and effectively narrow the buffer

zone of myocardial reserve. Occasionally, patients with persistent bleeding or other complicating factors, such as infection, may have an absolute or relative hypovolemia that magnifies that state of low cardiac output from ventricular dysfunction.

There are a number of factors specific to patients with hypoplasia of the left heart that may act in concert with post-bypass myocardial dysfunction to predispose to states of low cardiac output. Anatomically, the patients have a functionally single morphologically right ventricle. The structure of the right ventricle differs from that of the left ventricle in several respects, which may place it at a mechanical disadvantage with respect to pumping blood across the higher resistance systemic circulation. Similarly, because there is but a single functional ventricle, ventricular mechanics do not benefit from the right-left ventricular interaction that occurs in the presence of two normally proportioned ventricles.^{78,79} Moreover, the co-existence of a small left ventricle with a hypertrophied and low-compliance left ventricular mass that does not provide substantial systolic ejection may impair right ventricular diastolic function,⁸⁰ though recent work from Wisler and colleagues has suggested that the negative impact of a rudimentary left ventricle is most important just prior to the Fontan procedure, rather than after the first stage of reconstruction.⁸¹

Another anatomical issue that may affect ventricular function is impairment of coronary arterial flow.⁸² While this is in part a result of the anastomosis, there is little reserve diameter in the severely hypoplastic ascending aorta in some of these patients. In addition, patients with aortic atresia and mitral stenosis may have an intrinsically abnormal coronary arterial circulation,^{33,34,83} similar to the pattern in patients with pulmonary atresia and an intact ventricular septum.

Myocardial ischaemia during aortic crossclamping and circulatory arrest further contributes to impaired post-operative ventricular function.⁸² Myocardial ischaemia in the pre-operative period, more likely in patients with aortic atresia where coronary arterial flow is completely dependent upon patency of the arterial duct, and a late presentation, have an impact in the post-operative period, as coagulation necrosis and myocyte dropout evolve. This is compounded by intraoperative myocardial ischaemia, which may occur despite efforts at myocardial protection.

Maldistribution of Blood Flow

The other major category of factors that may contribute to low systemic perfusion is maldistribution of ventricular output. There are two primary situations in which this may occur: pulmonary over-circulation and valvar regurgitation. When a relatively large systemic-pulmonary arterial shunt is used, pulmonary over-circulation may be a significant problem. As already discussed, pulmonary over-circulation is less of a concern when a smaller shunt is placed, with its origin from the proximal subclavian artery or right ventricle. Although a mild degree of tricuspid or neo-aortic regurgitation is common, significant tricuspid or arterial valvar regurgitation is relatively rare.⁸⁴ The tricuspid valve, which serves as the systemic atrioventricular valve, is morphologically abnormal in as many as one-third of patients,⁸⁵ which may predispose to regurgitation. In addition, functional impairment of the

valve may occur, especially in patients with marked ventricular dysfunction and dilation. For example, patients who experience significant metabolic acidosis in the pre-operative period frequently have tricuspid regurgitation,⁸⁶ which may carry over into the post-operative period.

Evaluation of Low Cardiac Output

In the first 24 to 36 hours after surgery, patients are monitored closely for evidence of decreasing cardiac output and hypoxemia (Fig. 29-20). Haemodynamic parameters are monitored continuously, and the acid-base state and level of lactate in the serum are followed periodically to assess for hypoxaemia and inadequate delivery of oxygen. The difference in systemic arterial and venous saturations of oxygen, along with the ratio of systemic delivery to systemic consumption of oxygen, are useful measures to determine the adequacy of effective delivery. Also, as stated above, there is increasing interest in assessing systemic oxygen delivery non-invasively using near infrared spectroscopy. These parameters may become abnormal before indexes such as the level of lactate in the serum and the arterial base deficit.^{57,59} The arterial-venous difference is probably a more useful indicator in the setting of a functionally univentricular circulation,⁵⁷ though the validity of the systemic saturation in the superior caval vein as truly mixed venous blood is difficult to confirm.⁶⁷ The anaerobic threshold after first-stage palliation has been estimated to correlate with a systemic venous oxygen saturation of approximately 35%.⁸⁷ Electrocardiographic evidence of myocardial ischaemia or echocardiographic signs of depressed ventricular function may also indicate compromised myocardial blood flow before metabolic and oximetric measures. When it becomes apparent that systemic blood flow is decreased, supportive therapy is initiated and a specific cause is sought.

Echocardiography is performed to determine whether there is a specific anatomical cause of the decreased cardiac output. Features assessed include the quality of ventricular function, the competence of the tricuspid and arterial valves, the presence of a pericardial effusion, the appearance of the systemic-to-pulmonary arterial shunt and the interatrial septum, the aortic arch, and the native pathways to the ascending aorta and coronary arteries. If these anatomical features are all essentially normal, the ratio of flows is calculated with a combination of oximetric calculations and the Doppler echocardiographically derived index described above.³² Simultaneous with these investigations, laboratory studies are performed in order to ensure normal electrolytes, haematocrit, and acid-base state.

Management of Low Cardiac Output

Low cardiac output is managed according to the underlying cause (see Fig. 29-20). In most cases, this involves primarily support of cardiac function with positive inotropic agents and normalisation of blood pH, reduction of ventricular work by means of afterload-reduction, and minimisation of systemic demand for oxygen. The oxygen-carrying capacity of the blood is optimised by transfusion of packed red blood cells if the haematocrit is less than 40%.

In patients who develop acute decompensation due to potentially reversible myocardial dysfunction resulting from factors such as arrhythmia, discrete impairment of

Figure 29-20 Clinical presentation, diagnostic studies, and management algorithms for the child with evidence of low cardiac output following the first stage of reconstruction. (Modified from Wernovsky G, McElhinney D, Tabbutt S: Stage I postoperative management. In Rychik J, Wernovsky G [eds]: Hypoplastic Left Heart Syndrome. Boston: Kluwer, 2003.)

coronary arterial perfusion, or compromise of the systemic-pulmonary arterial shunt, mechanical circulatory support may be indicated. With prompt initiation in appropriately selected patients, extracorporeal membrane oxygenation has been shown beneficial.⁸⁸ If systemic perfusion is impaired as a result of increased volume load, systemic afterload reduction is increased by raising the dose of milrinone and/or initiating a continuous infusion of nitroprusside. If a correctable anatomical cause is identified, the appropriate invasive intervention is performed. If a pericardial effusion is detected, the chest is usually opened and the fluid drained, the patient is taken to the operating room or the chest opened at the bedside, depending on the urgency of the situation, in order to drain the fluid and identify and control the site of bleeding. If there is evidence of significant tricuspid or arterial valvar regurgitation, or of obstruction in the aortic arch (Fig. 29-21), the appropriate surgical intervention is performed.

As we have discussed, pulmonary over-circulation is uncommon after the initial stage of reconstruction when a restrictive systemic-to-pulmonary arterial shunt is used. In small patients, however, such a shunt may occasionally produce excessive flow to the lungs, as may a shunt of 4 mm diameter in larger neonates. In such circumstances, low systemic flow is managed initially by reducing systemic resistance by increasing the dose of milrinone, and/or by adding an infusion of nitroprusside infusion. Pulmonary resistance can be increased by using positive end-expiratory pressure, hypoxia, or hypercarbia.²⁷ Surgical revision of the shunt may also be considered.

Figure 29-21 This reconstructed computerized tomographic image shows a surgically reconstructed aortic arch. Note the discrepancy in size between the patch used to augment the ascending aorta, and the distal descending aorta. A moderate degree of obstruction is seen at the most distal end of the homograft patch, which was successfully relieved by balloon angiography. (Courtesy of Dr Jeffrey Hellinger, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania.)

Hypoxaemia

Pathophysiology of Post-operative Hypoxaemia

As summarised in Figure 21-19, systemic arterial oxygenation in patients with complete intracardiac mixing of blood is determined by three basic factors, namely, the

content of oxygen in the pulmonary veins, the systemic venous oxygen content, and the ratio of these two measures. When any of these is abnormally low, regardless of the state of the others, hypoxaemia may result. Not unexpectedly, therefore, hypoxaemia in the early post-operative period after the initial stage of palliation in neonates can be traced to conditions affecting one or more of these factors.

A decreased content of oxygen in the pulmonary veins results from suboptimal oxygenation of the blood leaving the lungs, and is relatively common.⁶² Potential causes of such poor oxygenation include intrapulmonary shunting, impaired exchange of gases due to pulmonary disease or oedema, and reduced effective lung volume resulting from pneumothorax or a pleural effusion, all of which may occur in the early post-operative period. Pulmonary venous desaturation without an identifiable cause may also be seen.⁶²

Systemic venous deoxygenation is most commonly due to low systemic flow and low cardiac output, as already discussed, but may also result from an abnormally low capacity to carry oxygen, or high systemic consumption of oxygen. Anaemia is the most common cause of decreased carrying capacity, while high consumption can be the result of inadequate sedation or paralysis, thermoregulatory drive, seizures, infection, or an accelerated catabolic state.

The commonest causes of decreased flow to the lungs are globally low cardiac output, which also affects the mixed venous saturation of oxygen, and technical problems with the systemic-to-pulmonary arterial shunt. Pulmonary vascular resistance typically fluctuates in the early post-operative period following neonatal repair, especially in the context of anomalies with high pre-operative pulmonary flow or obstructed pulmonary venous outflow. This is due to pulmonary vascular hyperreactivity, which is a complex phenomenon influenced by pulmonary endothelial dysfunction, itself resulting from high pre-operative and altered post-operative shear stress in the pulmonary circulation, as well as the pulmonary vascular effects of cardiopulmonary bypass and its adjunctive measures.⁶⁴ In order for endogenous pulmonary resistance to exert a substantial effect on the flow of blood to the lungs in patients with a restrictive systemic-to-pulmonary arterial shunt, it must be elevated well beyond the physiological range. Thus, increased resistance is rarely the sole factor responsible for significant hypoxaemia in this setting. It is more likely that problems with the systemic-to-pulmonary arterial shunt, rather than an elevated pulmonary resistance, will be responsible for reductions in flow that result in hypoxaemia. If elevated resistance is considered to be a factor in a patient with severe hypoxaemia, a trial of inhaled nitric oxide can be considered. In patients with labile pulmonary resistance, nitric oxide will improve systemic oxygenation. Lack of any response suggests a technical problem with the shunt, which may be compromised by constriction at either of the anastomotic sites, kinking, or partial or complete thrombosis, or simply because it is of insufficient diameter or excessive length to accommodate the necessary pulmonary flow in a given patient.

Evaluation of Post-operative Hypoxaemia

The cause of hypoxaemia can generally be distinguished by a combination of physical examination, chest radiography, pulse oximetry, and measurements of arterial blood gases,

combined with echocardiography with Doppler analysis of flows. Pulmonary causes of inefficient oxygenation are investigated with a combination of chest radiography, monitoring of ventilatory pressures and flow-volume relations, assessment of the function and pattern of drainage from the thoracostomy, and ultrasound, which can be an efficient means of evaluating a pleural effusion.

Decreased systemic venous oxygenation is determined by a combination of measurement of the haematocrit, venous co-oximetry, confirmation of paralysis and sedation, and exclusion of seizures or infectious causes of increased consumption of oxygen. If the patient is not anaemic, demonstrates no evidence of seizure activity or infection, and is adequately sedated and paralysed, the cause of decreased oxygenation is most likely poor ventricular function and/or cardiac tamponade, which is investigated and managed as described above.

Management of Post-operative Hypoxaemia

Management is tailored to the underlying cause. In patients with pulmonary venous desaturation due to extrinsic pulmonary compression, such as a pleural effusion or pneumothorax, the pleural fluid or air is drained with a small pleural catheter, which is left in place as necessary. Pulmonary parenchymal disease is treated with a combination of ventilatory manipulations and appropriate pharmacological therapy if indicated. Increased positive end-expiratory pressure can recruit atelectatic segments of lung, and facilitate improved ventilation-perfusion matching. It is effective at reducing pulmonary oedema.⁶² Increasing the fraction of inspired oxygen may also be effective at improving pulmonary venous desaturation.⁶²

Hypoxaemia due to decreased systemic venous saturation in association with low systemic flow is managed according to the principles discussed earlier. In patients with normal cardiac output but increased consumption of oxygen due to agitation, pain, and so on, pharmacological minimisation of systemic demand for oxygen, as with sedation and paralysis, is initiated or augmented. In patients with increased consumption due to infection, fever, or seizures, the underlying cause is treated with the appropriate measures.

Anatomical problems with the shunt causing inadequate flow to the lungs are managed with the appropriate intervention. Delivery of oxygen is generally optimised in patients with an obstructed shunt by administering volume, keeping the systemic arterial pressure high, ensuring adequate sedation, and providing supplemental oxygen. If the shunt is obstructed, management is with surgery or interventional catheterisation in most cases. If acute deterioration occurs, resuscitation with extracorporeal oxygenation may be necessary.

Summary

The goals of the first 24 hours of post-operative care include supporting combined cardiac output with inotropes and reduction of systemic afterload, minimizing the demand for oxygen with sedation and occasionally neuromuscular blockade; minimizing stressful procedures that increase such demand, taking note of pulmonary and systemic vascular resistances; treating pain; and anticipating common complications, and managing them promptly. The cost of this strategy is the need for indwelling invasive catheters, mechanical ventilation, and medications with potentially important toxicities. Equally important in optimizing recovery following the first stage of palliation is appropriate

management of the second phase of post-operative care, when myocardial function has returned to baseline and vascular resistances have stabilised. This requires the prompt removal of invasive catheters and tubes, and the weaning of pharmacological support, in other words, de-intensification.

SUBACUTE/STEPDOWN MANAGEMENT

De-intensification

In the patient with an uncomplicated acute post-operative course, we begin preparing for step-down management approximately 16 to 20 hours after surgery, a strategy that is based on the typical post-operative haemodynamic profile as discussed above. Although myocardial function and cardiac output may not have fully normalised by this point, the trend is towards improved cardiac function. De-intensification can then be initiated in anticipation of normalised haemodynamics. This strategy decreases the likelihood of iatrogenic complications without sacrificing optimal care during the critical acute post-operative period.

If utilised, neuromuscular blocking agents are generally discontinued within 12 to 18 hours after the operation, with return of spontaneous breathing within the next 12 to 24 hours, depending on the renal function and drug clearance. The level of mechanical ventilatory support is gradually decreased, and the patient extubated 1 or 2 days after surgery. Following extubation, intravenous inotropic and afterload-reducing medications are weaned, as diuretic medications, and occasionally digoxin, are continued. Once inotropic agents and afterload-reducing medications are discontinued, the umbilical and urinary catheters are removed. Right atrial catheters are typically maintained to provide parenteral nutrition until full enteral feeds are tolerated. Routine laboratory studies are decreased in frequency and scope during the course of de-intensification, and usually obtained only once a day following removal of the indwelling vascular catheters. Enteral feeding is initiated once inotropic support has been weaned and the umbilical arterial catheter has been removed. The goal is to complete the process within 4 to 5 days of admission to the intensive care unit following surgery.

Feeding and Necrotizing Enterocolitis

Enteral nutrition is usually initiated with continuous nasogastric feeds, with a steady increase in the rate until gastrointestinal tolerance has been amply demonstrated. Most patients are also maintained on ranitidine. Parenteral nutrition is gradually decreased in accordance with the advance in feeding, and discontinued once the patient is tolerating enteral feeds sufficiently to meet the full nutritional requirement. The transition is then made to intermittent nasogastric feeds, and oral feeds are introduced gradually. Neonates frequently have difficulty resuming normal oromotor and pharyngeal coordination after the first stage of palliation, and feeding is often impaired.⁸⁹ Evaluation of the left vocal cord should also be considered in patients who demonstrate coughing or respiratory distress with oral feeds. Although patients are given every opportunity to meet their nutritional needs with oral feeding,

approximately two-fifths of those undergoing the first stage of palliation at our centre are ultimately discharged on a regime of supplemental nasogastric feeding, or have a gastrostomy tube placed. All patients with congenitally malformed hearts are a population at nutritional risk,^{90,91} and supplemental tube feeding has been demonstrated to benefit such infants.⁹²

One of the most important considerations in resuming enteral feeds after the initial stage of reconstruction is the possibility of necrotizing enterocolitis. Over a 4-year period, almost one-twenty-fifth of neonates with congenitally malformed hearts admitted to our cardiac intensive care unit developed this complication, with those having hypoplasia of the left heart being at significantly increased risk.⁹³

Intermediate Outcomes Following First-stage Reconstruction

Following hospital discharge, infants who have undergone the first stage of reconstruction remain at risk for haemodynamic compromise, as mentioned above. Residual or recurrent obstruction to systemic blood flow may occur in up to 1 in 10 infants, requiring balloon angioplasty⁹⁴ or surgical revision. Following the second stage of reconstruction, later mortality is rare, on-going monitoring is rarely necessary, and growth and development improve. In the 25 years since the first successful reports of palliation for hypoplasia of the left heart, infants and children have been shown to have a similarly low risk of later mortality compared with other children with functionally univentricular hearts who have undergone staged reconstruction culminating in a Fontan procedure. Surgical mortality for the second- and third-stage procedures are less than 5% in most reported series, and late death has been rare.⁹⁵⁻⁹⁷

The protean cardiovascular and non-cardiovascular morbidities following the Fontan procedure have been well documented.^{54,98,99} At the current time, most of these important morbidities, including arrhythmias, hypercoagulability and thrombosis, protein-losing enteropathy, plastic bronchitis, and a reduced ability to exercise, occur in similar frequencies in children with hypoplasia of the left heart and those with other forms of functionally univentricular hearts. The only two exceptions to this generalisation are the potential for dilation of the neo-aortic root, and the increased frequency of impairment to the central nervous system, as discussed in Chapter 64.

Progressive dilation of the anatomical pulmonary valve and root has been reported,¹⁰⁰ with progressive regurgitation of the neo-aortic valve in some children, including isolated case reports of replacement of the neo-aortic valve in children and adolescents with hypoplasia of the left heart following staged reconstruction. It is likely that the frequency of this complication will increase with increasing duration of follow-up, as has been seen following the arterial switch and Ross operations. Finally, children with hypoplasia of the left heart are more likely than others with congenital cardiac malformations to have microcephaly at birth, other structural abnormalities of the brain at birth, and genetic syndromes. School-age children with hypoplasia of the left heart have an increased prevalence of attention, behavioural, and learning disorders compared to the normal population, as well as to other children who have undergone the Fontan procedure with other forms of functionally univentricular heart.

Using a previous technique reported to be successful by Gibbs and colleagues, a series of patients with hypoplasia of the left heart underwent stenting of the arterial duct and banding of the pulmonary arteries in Geissen, Germany. Of the patients, one died 4 months after the procedure whilst awaiting cardiac transplantation. A second death occurred in a patient after the second stage of palliation, consisting of reconstruction of the aortic arch and a superior cavopulmonary anastomosis. These improved outcomes promoted further interest in this strategy.
- Sano S, Ishino K, Kawada M, et al: Right ventricle–pulmonary artery shunt in first-stage palliation of hypoplastic left heart syndrome. *J Thorac Cardiovasc Surg* 2003;126:504–509.
This report established the concept of placing a conduit from the right ventricle to the pulmonary arteries as the source of pulmonary flow in infants who undergo the modified Norwood procedure. In the hands of the authors, this approach improved early survival to 89%, in comparison to previous survival of no more than 50% using the standard Norwood procedure. They describe their surgical technique in detail.
- Ghanayem NS, Hoffman GM, Mussatto KA, et al: Home surveillance program prevents interstage mortality after the Norwood procedure. *J Thorac Cardiovasc Surg* 2003;126:1367–1377.
With improvement in outcomes over time, interstage mortality between initial and subsequent palliative surgeries was identified to be important, with deaths between stages approaching surgical mortality for the initial palliation. In this study, the group from Milwaukee describes a methodology for improving interstage mortality using a programme of home surveillance. Additionally, the authors suggest not delaying the second-stage palliation beyond 5 to 6 months, since a plateau in weight gain was identified at this age.

This article reviews the literature and nicely summarises important aspects for long-term survivors with functionally univentricular hearts who have undergone staged palliation or cardiac transplantation. Important issues such as medical and functional state are covered.
- Migliavacca F, Pennati G, Dubini G, et al: Modeling of the Norwood circulation: Effects of shunt size, vascular resistances, and heart rate. *Am J Physiol Heart Circ Physiol* 2001;280:H2076–H2086.
This article presents a mathematical model of the circulation after a Norwood procedure, and examines the effect of three significant variables. The results have important clinical implications with regard to monitoring and post-operative therapies in the intensive care unit.
- Tweddell JS, Hoffman GM, Fedderly RT, et al: Patients at risk for low systemic oxygen delivery after the Norwood procedure. *Ann Thorac Surg* 2000;69:1893–1899.
This paper highlights the importance of systemic delivery of oxygen in the post-operative period after the Norwood procedure. This is one of a series of papers from this group, suggesting a change in style of management from focusing on balancing the pulmonary and systemic circulation to focusing on the systemic circulation. The authors identify lower mixed venous saturations of oxygen in the groups of patients with a high risk of death.
- Bartram U, Grunenfelder J, Van Praagh R: Causes of death after the modified Norwood procedure: A study of 122 postmortem cases. *Ann Thorac Surg* 1997;64:1795–1802.
Identifying the causes of death after the Norwood procedure may help in treating or evaluating sick patients. This study reviews the causes of death in 122 patients after the Norwood procedure at Boston Children's Hospital. The authors identify that over one-half the deaths were related to surgical technical issues, or with perfusion of the lungs or myocardium.
- Skinner ML, Halstead LA, Rubinstein CS, et al: Laryngopharyngeal dysfunction after the Norwood procedure. *J Thorac Cardiovasc Surg* 2005;130:1293–1301.
A significant portion of inpatient stay after the Norwood procedure often relates to issues relating to feeding or the airways. In this investigation, the authors identified a high rate of feeding issues, including abnormal swallowing in one-half the patients and aspiration in one-quarter, with paralysis of the vocal cords in one-tenth. They also discuss the natural history of these problems.
- Zeltser I, Menteer J, Gaynor JW, et al: Impact of re-coarctation following the Norwood operation on survival in the balloon angioplasty era. *J Am Coll Cardiol* 2005;45:1844–1848.
The investigators review the important complication of re-coarctation in a large series of patients who underwent the Norwood procedure. Re-coarctation occurred in one-tenth of the cohort, and recurred in one-fifth of these patients. Balloon angioplasty proved successful as treatment for the majority of these patients, and was achieved with low morbidity.

CHAPTER 30

Hypoplasia of the Right Ventricle

PIERS E.F. DAUBENEY

The right ventricle can be hypoplastic in various settings. It can be small in the presence of deficient ventricular or atrioventricular septation, producing so-called left ventricular dominance. The chamber can also be small and incomplete in the setting of univentricular atrioventricular connections such as double inlet left ventricle or tricuspid atresia. The ventricle can be hypoplastic when the ventricular septum is intact and there is so-called critical stenosis of the pulmonary valve. All of these entities are dealt with elsewhere in this book. In this chapter, we are concerned with pulmonary atresia in the setting of an intact ventricular septum (Fig. 30-1), and have included the situation in which the cavity of the right ventricle is dilated, as well as hypoplastic. Almost invariably the heart is left-sided, with concordant atrioventricular and ventriculo-arterial connections, but rarely pulmonary atresia can be found in the setting of an intact ventricular septum when the ventriculo-arterial connections are discordant. In these cases, of course, it is left ventricular hypoplasia which dominates the picture, typically with the ventricle having a fibroelastotic lining as

is the case in hypoplasia of the left heart with usual segmental combinations (see Chapter 29). Pulmonary atresia itself can also occur in various additional settings, such as when the intracardiac anatomy is that of tetralogy of Fallot, and in conjunction with other complex lesions such as atrioventricular septal defect, isomeric atrial appendages, or discordant ventriculo-arterial connections. In all of these situations, however, ventricular septation is deficient. When seen with an intact ventricular septum, there is considerable diversity of the morphology of the tricuspid valve, the right ventricle, and the pulmonary arteries, as well as frequent coronary arterial abnormalities. In two of the final encyclopaedic reviews led by Freedom,^{1,2} attention was directed to the huge problems produced by lesions of the coronary arteries or tricuspid valve in this setting, making it one of the most lethal of current congenital cardiac malformations. It was not without reason that Freedom³ had previously commented, in one of his many perceptive reviews of this lesion, 'How can something so small cause so much grief?' I will deal with all of these aspects in the sections that follow.

Figure 30-1 The cartoon shows the basic arrangement of pulmonary atresia with intact ventricular septum when the right ventricular cavity is hypoplastic rather than dilated.

GENETICS, EMBRYOGENESIS AND INCIDENCE

Pulmonary atresia with intact ventricular septum is a relatively uncommon disease accounting for about 3% of serious congenital heart disease at birth.⁴ It is the third most common type of cyanotic congenital cardiac malformation in neonates, coming after transposition and tetralogy of Fallot with pulmonary atresia.⁵ The distribution according to gender was 1.5 males to 1 female in the population-based study carried out in the United Kingdom and Eire from 1991 through 1999, with figures of 1.3:1 in the Swedish based study.⁶ The estimated prevalence at birth from the various epidemiological studies varies from 4.2 to 8.5 per 100,000 live births.⁶⁻¹²

These data, of course, reflect the prevalence of the disease at birth. The advent of fetal echocardiography has shown that there may be significant spontaneous death prior to this during fetal life. In particular, those fetuses with severe tricuspid regurgitation seem to have a poor outcome, often developing hugely dilated atriums, hypoplasia of the lungs, atrial arrhythmias, ascites, and pleural and pericardial effusions.¹³⁻¹⁸ It was predicted that fetal echocardiography would lead to a substantial reduction in the prevalence of complex congenitally malformed hearts seen at birth because of selected termination of pregnancy.¹⁹ This was confirmed in the collaborative study performed in the United Kingdom and Eire,⁹ with only about one-third of those diagnosed during life surviving to become live births.⁹

The prevalence at birth in mainland Britain was estimated to have fallen by 26% because of fetal diagnosis.

MORPHOGENESIS AND AETIOLOGY

Morphogenesis

As for many types of congenital heart disease, the morphogenesis of the lesion is unclear, although the morphology dictates that the insult producing the atresia must have occurred after the completion of ventricular septation. There is some evidence as to the timing of this developmental insult. Several groups have examined various morphological features, including the size and morphology of the pulmonary valve, and the topology of the arterial duct.^{20–22} The angle subtended by the duct to the postductal descending aorta may be an indicator of whether the pulmonary arterial pathways became atretic earlier or later in gestation. In normal hearts, the duct runs almost parallel with the transverse arch, forming an obtuse angle with the postductal aorta (Fig. 30-2). In pulmonary atresia in the setting of deficient ventricular septation, the duct may originate more proximally on the aortic arch than normal, is usually sigmoid in shape, and subtends an acute angle to the postductal aorta. This led to the hardly surprising suggestion that the atresia develops early in these lesions during cardiac morphogenesis, at or shortly after partitioning of the outlets of the developing heart, but before closure of the embryonic interventricular communication.²¹

Figure 30-2 These echocardiograms show the variation in ductal angle. A, A normal angle between the arterial duct and the descending aorta (DAO), of greater than 90 degrees, in a patient with a tripartite right ventricle and an imperforate pulmonary valve. B, An acute angle, of less than 90 degrees, in a patient with unipartite right ventricle and muscular atresia. The arrows superimposed on these echocardiograms show the variation in ductal angle. AO, aorta; LA, left atrium. (From Daubeney PE, Delany DJ, Anderson RH, et al: Pulmonary atresia with intact ventricular septum: Range of morphology in a population-based study. *J Am Coll Cardiol* 2002;39:1670-1679.)

In those in whom the ventricular septum is intact, the duct subtends a highly variable angle to the postductal aorta. Patients with better developed right ventricular cavities tend to have ducts subtending normal angles, whilst in those with severely hypertrophied ventricles, and ventricular-to-coronary fistulous connections, it tends to be acute²³ (see Fig. 30-2), supporting the notion that those with smaller and hypertrophied right ventricles suffered their developmental insult earlier in gestation than did those with ventricles having better developed cavities.²⁴ This notion has now been supported by evidence from fetal echocardiography, where progression from pulmonary stenosis to atresia has been documented during later pregnancy.^{9,17}

Previously, it was assumed that atresia of the pulmonary valve was the primary morphogenetic event, leading to right ventricular hypertension, and development of the fistulous communication with the coronary arteries. More recently, several groups have suggested that, at least in those with fistulous connections, the primary disease may be one of persistence of these communications,²⁵ or abnormal morphogenesis of the right ventricle,²⁶ rather than the pulmonary valve itself. As fistulous communications have been identified from 13 weeks gestation onwards, and as it is known that the embryonic interventricular communication closes in the ninth week, Chaoui and colleagues have doubted that this leaves enough time for right ventricular hypertension to cause the development of fistulas.²⁵ Their argument goes on to state that, as prenatal afterload is higher in the right ventricle compared to the left,^{27,28} blood would preferentially pass through the fistulous communications, rather than the pulmonary valve, leading to pulmonary stenosis and atresia. As an alternative they suggested that there may be a primary insult at right ventricular level, leading to both pulmonary atresia and to persistence of the communications from the right ventricle to the coronary arteries,²⁵ a concept also supported by Bonnet and colleagues.²⁶ The concept has now been further extended by Gittenberger-de Groot and her colleagues,^{29,30} who refute the suggestion that the pulmonary valve is the site of the primary abnormality. Her group propose that the primary anomaly in this subset of patients is lack of ingrowth of the developing coronary arteries even prior to development of pulmonary atresia, since the coronary vasculature develops from the epicardium, and not from the intertrabecular spaces.^{31,32} They also highlighted the role of cells migrating from the neural crest in this process of vascular development.³⁰ The likely morphogenesis has been summarised neatly by Bonnet and colleagues as a 'primitive alteration of a mechanogenic transduction pathway, crucial for right myocardial remodelling during embryogenesis'.²⁶

Aetiology

The underlying abnormality in this condition has not been elucidated. Both congenital and acquired aetiologies have been proposed.^{21,33} Some thought that the coronary arterial pathology seen represented an endarteritis,³⁴ while others proposed that a prenatal inflammatory disorder may cause the development of atresia.²¹ This has not been supported by any histological evidence of an acute or subacute disorder, either pre- or postnatally.^{2,15,17} There is some evidence showing that the lesion can be acquired during fetal life in association with twin-to-twin transfusion.³⁵ Twinning

studies have also demonstrated an excess of congenitally malformed hearts in monozygotic twins, often in only one of the set of twins,³⁶ leading to the suggestion that the twinning process itself may lead to increased congenital cardiac malformations, possibly due to loss of laterality in one twin. Furthermore, siblings have been described, both having the lesion, suggesting an autosomal recessive trait, with doubt being expressed as to whether the disease can really be acquired.³⁷ It seems likely, therefore, that the morphological entity represents a common endpoint for a range of underlying disorders, both hereditary and acquired during fetal life.

MORPHOLOGY

The lesion is a global condition affecting the entirety of the right ventricle.^{38–40} The extent of morphological heterogeneity is illustrated by the frequency in which each anatomical feature occurs within the United Kingdom and Eire population-based study²³ (Table 30-1) This can then serve a reference to ensure that future studies are reflective of the population as a whole.

Tricuspid Valve

Almost invariably, the right ventricular inlet valve is abnormal.^{38,41–47} Abnormalities can include dysplasia, Ebsteinoid displacement, and a wide range of annular size, ranging from tiny to hugely dilated. Often the valve shows all three abnormalities to a variable degree. At a functional level, there is a continuum from severely stenotic to freely regurgitant.

Tricuspid stenosis at its most severe may be due to an obstructed muscularised annulus with dysplasia of the valvar leaflets and their supporting tension apparatus.⁴⁵ The free edges of the leaflets may be thickened and nodular, the cords reduced in number, and shortened with fibrous thickening. The papillary muscles can be underdeveloped with abnormal attachments.⁴⁷ Even the most severely stenotic tricuspid valve is likely also to have a degree of regurgitation.⁴⁵

Tricuspid regurgitation at its most severe may be accompanied by a grossly dilated annulus, with displacement and severe dysplasia of the tricuspid valvar leaflets (Table 30-2).^{23,37} At its extreme, the tricuspid valve may be devoid of all leaflet tissue, leaving an unguarded tricuspid valvar orifice, and leading to a hugely dilated and thin-walled right ventricle.^{47–50} Ebstein's malformation is seen in about one-tenth of cases^{23,49} (see Table 30-1), and can be found with both hypoplasia (Fig. 30-3) and dilation of the right ventricular cavity. In the setting of a dilated cavity, there is sail-like enlargement of the antero-superior leaflet, whereas when the ventricle is hypoplastic, the changes are confined to downward displacement of an often dysplastic septal leaflet.⁴⁷ Whereas Ebstein's malformation usually leads to a regurgitant valve, the displaced valve may also be virtually imperforate when the cavity is hypoplastic.⁴⁴

Severe tricuspid regurgitation, whether due to dysplasia or Ebstein's malformation, can lead to functional pulmonary atresia.^{51–53} This occurs when the right ventricle is unable to generate sufficient pressure to open an anatomically normal pulmonary valve. Distinguishing functional from true atresia can be difficult. It normally relies on the fact that there is a degree of diastolic regurgitation through the pulmonary valve that can be seen echocardiographically^{54–56} or angiographically.⁵⁷

The size of the tricuspid valve correlates well with the size of the right ventricular cavity^{23,38,43,44,47,58–60} (see Table 30-2), unlike the situation in critical pulmonary stenosis.⁶¹ This correlation, and the importance of the right ventricular inlet in surgical repair, has led to several groups advocating use of the dimensions of the tricuspid valve as a guide to surgical management.^{60,62–74} This is usually based on the z score, the number of standard deviations a measurement departs from the mean normal. Several nomograms are available for these derivations.^{75,76} Caution must be adopted, nonetheless, in interpreting these z scores, as they are not always comparable. Some depend on normal data obtained from echocardiographic studies,⁷⁵ while others come from postmortem studies of formalin-fixed hearts.⁷⁷

TABLE 30-1

SUMMARY OF PRINCIPAL MORPHOLOGIC FINDINGS IN THE POPULATION-BASED STUDY CARRIED OUT IN THE UNITED KINGDOM AND EIRE FROM 1991 THROUGH 1995

Morphologic Feature	Type	Number
Type of pulmonary atresia	Membranous	130/174 (74.7%)
	Muscular	44/174 (25.3%)
Partite state of the RV	Tripartite	84/143 (58.7%)
	Bipartite	48/143 (33.6%)
	Unipartite	11/143 (7.7%)
Coronary arterial abnormalities	RV-to-coronary fistulas	60/132 (45.5%)
	Coronary arterial stenoses, interruption and ectasia	10/132 (7.6%)
Ebstein's malformation		18/183 (9.8%)
Significant RV dilatation		8/183 (4.4%)
Size of tricuspid valve	Median z score: echo*	−5.2 (range: −18.3 to 9.4)
	Median z score: autopsy†	−1.6 (range: −2.9 to −0.4)
Size of RV inlet	Median z score*	−5.1 (range: −16.0 to 3.5)

*z scores calculated from echocardiographically-derived normal values,⁷ rather than †postmortem-derived normal values.⁷⁷ In all, 15 abnormalities of the left ventricle were documented, including 4 with extreme septal hypertrophy with bulging into the left ventricular outflow.

RV, right ventricle.

From Daubeney PE, Delany DJ, Anderson RH, et al: Pulmonary atresia with intact ventricular septum: Range of morphology in a population-based study. *J Am Coll Cardiol* 2002;39:1670–1679

TABLE 30-2

INTER-RELATIONS OF MORPHOLOGIC VARIABLES AT PRESENTATION FROM THE UNITED KINGDOM AND EIRE POPULATION-BASED STUDY

	RV Inlet z Score (Increased Inlet Length)	Ductal Angle (Normal)	Fistulae (Absence)	Type of Atresia (Membranous)	Partite (Tripart)	Stenoses (Absence)	Tricuspid Regurg. (Increased)	RV pressure (Lower)
TV z score (increased valve size)	$P < 0.0001$ $R = 0.45$	$P = 0.0120$	$P < 0.0001$	$P < 0.0001$	$P < 0.0001$	$P = 0.1763$	$P = 0.0050$	$P = 0.0011$ $R = 0.402$
RV inlet z score (increased inlet length)		$P = 0.3304$	$P = 0.0011$	$P = 0.0131$	$P < 0.0001$	$P = 0.5755$	$P = 0.0052$	$P = 0.7459$ $R = 0.041$
Ductal angle (normal)			$P = 0.0095$	$P < 0.0001$	$P < 0.0001$	$P = 0.0852$	$P = 0.0743$	$P = 0.3077$

There is considerable covariance of morphologic features: for example a small right ventricle will tend to have muscular atresia and a small tricuspid valve. Such covariance is shown in this table. This table shows, for a population of patients with pulmonary atresia with intact ventricular septum at presentation, the p value for the presence, absence (or other denoted state) of key morphologic features co-existing in the same heart.

RV, right ventricle; TV, tricuspid valve.

From Daubeney PE, Delany DJ, Anderson RH, et al: Pulmonary atresia with intact ventricular septum: Range of morphology in a population-based study. *J Am Coll Cardiol* 2002;39:1670–1679

Figure 30-3 In this heart with obliteration of the apical component, and hypoplasia of the outlet component, the tricuspid valve shows evidence of Ebstein's malformation, with the septal leaflet hinged away from the atrioventricular junction (yellow dotted line).

Right Ventricle

Although the initial classification of the right ventricle was into small as opposed to normal or dilated categories,⁷⁸ this concept has now been refined to acknowledge the

continuum in right ventricular size.^{44,79} When the right ventricle is said to be hypoplastic, it is not the ventricle itself that is hypoplastic, but rather the ventricular cavity that is obliterated by the severe muscular hypertrophy. Using the observations of Goor and Lillehei, that normal right ventricle has three parts,⁸⁰ Bull and colleagues proposed the tripartite approach to categorisation of pulmonary atresia with intact ventricular septum, and this was subsequently used as the basis for surgical decision-making.^{63,81} Patients were categorised as to the degree of mural hypertrophy present, giving the following options:

- All three portions of the right ventricle cavity being well-formed, with minimal mural hypertrophy (Fig. 30-4).
- Muscular overgrowth of the apical trabecular portion. The cavity in this setting is effectively formed by the inlet and outlet components, with the infundibulum still extending to the undersurface of the imperforate valve, but through a very narrow channel. The inlet component also becomes hypoplastic, with the tricuspid valve usually tethered by short cords to the margins of the obliterated apical component (Fig. 30-5). Although the cavity effectively has only two components, all three initial parts of the morphologically right ventricle are readily identified.
- Muscular overgrowth of both apical and outlet portions. It is this process that produces the severest examples of the lesion, with the cavity in this setting effectively represented only by the hypoplastic inlet component (Fig. 30-6). Even with this arrangement, nonetheless, all three portions of the right ventricle are present, with the cavities of the apical trabecular and outlet parts being obliterated.

Management of these patients, be it by surgical or interventional catheterisation techniques, requires selection of

Figure 30-4 In this heart, the pulmonary valve is imperforate, but all three parts of the ventricular cavity are well-formed. Note the relatively normal tricuspid valve.

Figure 30-5 In this heart, mural hypertrophy has obliterated the apical component of the right ventricle, the cavity being represented by the hypoplastic outlet and inlet components. Note the abnormalities of the tricuspid valve.

Figure 30-6 Mural hypertrophy in this heart has squeezed out the apical and outlet components, leaving the ventricular cavity represented only by the inlet.

patients with suitably sized right ventricles in early life. Numerous attempts have been made to assess the adequacy of the right ventricle in order to guide the optimal strategies for management.^{6,38,60,62,65,71,72,81-94} Owing to the fact that the walls of the right ventricle are usually severely hypertrophied, with sometimes bizarrely irregular cavities, quantification of size may be inaccurate, particularly when assessed using methodologies designed for the left ventricle.^{38,95} The advantage of the tripartite approach to classification³⁸ is that, following angiography, the ventricles can be relatively easily grouped into subtypes. This may be more clinically relevant than estimations of volume. Thus, about three-fifths of cases have the so-called tripartite arrangement, about three-tenths have bipartite cavities, and just under one-tenth have the unipartite form.²³ The disadvantage of this classification is that it is qualitative, and perhaps oversimplistic.⁴⁰ Deciding how much muscular overgrowth of the apical region of the right ventricle is needed to make a right ventricle bipartite as opposed to tripartite is very subjective. Furthermore, there is a great deal of variability in size within a subtype. So-called tripartite right ventricles can range from having severely hypoplastic to hugely dilated cavities. It has also been observed that the degree of muscular hypertrophy can increase over time, both pre- and postnatally.^{17,39} Despite these limitations, the partite classification is of considerable use. Its ultimate utility may be as one of several morphological markers for the state of the right ventricle, that can be used in combination as independent risk factors for analysis of procedural outcomes.

Dilation of the right heart occurs in just under one-twentieth of cases,²³ and is caused by a tricuspid valve with either severe Ebstein's malformation (Fig. 30-7), or significant tricuspid valvar dysplasia,¹⁵ both these lesions leading to severe tricuspid regurgitation. The dilation of the cavity occurs during fetal life, so that, at birth, the heart fills the entirety of the thoracic cavity, producing the so-called wall-to-wall arrangement¹ (see Fig. 30-7). The right ventricle is still tripartite because none of its portions are overgrown with muscle. It is also very thin-walled, particularly the atrialised portion if there is tricuspid valvar displacement.⁹⁵ These hearts may have minimal inlet and trabecular myocardium, superficially resembling hearts with Uhl's anomaly.^{96,97} They should not, however, be described in this fashion, since the changes are the consequence of right ventricular dilation, whereas the anomaly described by Uhl is due to congenital absence of the right ventricular parietal musculature. The dilated ventricles seen with pulmonary atresia have low pressures, and hence do not develop right ventricular to coronary arterial fistulous connections (see Table 30-2). The consequence of the gross dilation of the heart is that the lungs become squeezed during fetal life, and do not develop properly. All the component parts are present, but they are unable to expand in appropriate fashion because almost all the space within the thorax is occupied by the heart.¹⁵

When the right ventricle is very hypertrophied, often in conjunction with tricuspid stenosis, there may be supra-systemic right ventricular pressure, assuming insignificant tricuspid regurgitation (see Table 30-2). It is these hearts that typically are associated with numerous fistulous communications between the ventricular cavity and the coronary arteries, and which can exhibit a right ventricular dependent coronary arterial circulation.

Figure 30-7 A, A typical wall-to-wall heart. The lungs are not seen, being squeezed out by the huge size of the dilated right-sided chambers of the heart. B, Opening the heart shows marked displacement of the hingelines of the leaflets of the tricuspid valve away from the atrioventricular junction (red dotted line), the hallmark of Ebstein's malformation.

At a histological level, a wide range of abnormalities of the right ventricle have been found, including subendocardial and transmural ischaemia, fibrosis, infarction, so-called spongy myocardium, myocardial disarray, and endocardial fibroelastosis.^{1,2,29,39,44,46,95,98–106} There is an inverse relationship between endocardial fibroelastosis and the presence of fistulous coronary arterial connections, albeit that the reason for this is unknown. It may be that the endocardial fibroelastosis blocks the communications during their development, or alternatively that the communications may decompress the right ventricle, hence preventing the development of endocardial fibroelastosis.^{103,107} Ischaemic changes to the right ventricle can be seen even in the absence of fistulous connections.¹⁰⁴

At a functional level, it is not surprising that the right ventricle shows disorders of both systolic and diastolic function.^{105,108,109} Even after complete biventricular repair, diastolic abnormalities have been documented, with antegrade diastolic flow occasionally being found in the pulmonary trunk.¹⁰⁹

The Right Ventricular Infundibulum

As with the tricuspid valve and the right ventricle, there is a wide spectrum of morphology of the infundibulum. This can range from a patent infundibulum of normal size extending to an atretic valvar membrane¹¹⁰ (Fig. 30-8), to its complete obliteration by muscular hypertrophy (see Figs. 30-6 and 30-9). The latter arrangement produces the so-called unipartite arrangement of the ventricular cavity³⁸ (see Tables 30-1 and 30-2). Membranous atresia is found in three-quarters of cases, and muscular in the remainder.²³ In the cases with a well-formed infundibulum, the pulmonary valvar remnant shows evidence of the initial three leaflets, fused along their zones of apposition into a fibrous plate,^{44,58,110–112} with raphe showing the sites of fusion (Fig. 30-8B), albeit on occasion the zones of fusion can suggest an initial bifoliate, or even a quadrifoliate valve.

When the outlet component is also obliterated, it is not possible to trace a patent infundibulum to the

Figure 30-8 A, An infundibulum (arrow) that is patent to the level of an imperforate valve. B, When viewed from the arterial aspect there is evidence that the valve initially possessed three leaflets, the sites of attachment to the sinutubular junction being readily apparent (stars).

ventriculo-arterial junction, although evidence of the channel initially present can be seen in dissected hearts (see Fig. 30-6). When examined from the arterial aspect, it can be seen that the pulmonary trunk retains its origin from the right ventricle (see Fig. 30-9), so that the ventriculo-arterial connections remain effectively concordant. The blind-ending pulmonary trunk originates above the triradiating sinuses, with remnants centrally showing that, initially, the root did support valvar tissue (see Fig. 30-9). Assessment of the size of the right ventricular outflow is of great importance when contemplating either surgical or catheter manoeuvres to enlarge the outlet component. Indeed, several groups have advocated taking the size of the outflow tract as a means of determining the best strategy for management.^{38,63,81,83,85,86,88,91,113}

Pulmonary Arteries

The pulmonary arteries are usually confluent, and supplied by a left-sided arterial duct.³⁷ Should systemic-to-pulmonary arteries be encountered, then suspicion should be raised

Figure 30-9 In these images, from patients with muscular atresia and unipartite ventricle, the pulmonary trunk has been dissected to show the evidence of sinuses of Valsalva, but absence of any leaflets of the pulmonary valve (A) and minimal formation of the leaflets (B).

that, initially, there was an interventricular communication, but that the hole between the ventricles closed during fetal life. The pulmonary trunk is usually mildly hypoplastic or of normal size (Fig. 30-10A), although it may, rarely, be small or even no more than a thread-like solid cord (Fig. 30-10B). The dimensions of the pulmonary trunk and

arteries may be unrelated to the size of the right ventricular cavity.^{44,111} Even those with a tiny right ventricle can have a pulmonary trunk of near-normal size. When the right ventricle is excessively dilated, the pulmonary arteries tend to be severely hypoplastic, with greatly reduced volumes of the pulmonary parenchyma.

Figure 30-10 The figures show the variability in dimensions of the pulmonary trunk. Usually it is no more than mildly hypoplastic (A), but it can rarely be a solid cord (B). Note that in both instances pulmonary arterial supply is through the persistently patent arterial duct.

Left Ventricle and Mitral Valve

The mitral valve is usually normal, but dysplasia has been documented.^{112,114} The left ventricle is often dilated, with a degree of mural hypertrophy,^{112,114} and may exhibit disorders of systolic and diastolic function.^{105,108,115–118} With a severely hypertensive right ventricle, the ventricular septum may bulge into the left ventricular outflow tract, thus providing the substrate for subaortic obstruction,^{44,112,114} particularly after the Fontan procedure,¹¹⁹ but only rarely before.^{23,120}

At a histological level, abnormalities of the left ventricle may comprise myocardial disarray, non-compacted myocardium, and endocardial fibroelastosis.^{44,101,105} An increase in collagen in the subendocardial layer has been implicated as suggesting chronic ischaemia, indicating that the left ventricle may be the limiting factor for long-lasting intervention.¹¹⁴ Abnormalities of contractility and efficiency noted in patients after the bidirectional Glenn and total cavopulmonary procedures, unrelated to fistulous connections, have also been related to the impact of the high-pressure residual right ventricle impairing left ventricular performance.¹¹⁸ Abnormalities of the aortic valve have been reported, even critical aortic stenosis.¹²¹ They are rare, but if severe, presage a poor outcome.^{112,122–124}

Coronary Arterial Circulation

What sets this lesion apart from most other congenital cardiac disorders is the high incidence of coronary arterial abnormalities.^{23,60} These changes were first described in 1926, in a 14-month-old who had intermuscular spaces with free communications between the right ventricular cavity and the coronary arteries.¹²⁵ Over the next 50 years, appreciation of their significance changed from innocent bystanders to a major potential cause of myocardial ischaemia.¹²⁶ The abnormalities involve disorders of origin and distribution of the coronary arteries, fistulous connections to the right ventricle, absence of proximal connections to the aorta, stenoses or interruption, and hugely dilated ectatic segments. Although some use the term ventriculo-coronary connections synonymously with coronary artery fistulas, a distinction should be drawn between blind-ending sinusoids that may connect to the myocardial capillary bed, but not the coronary arteries, and those connections which are direct communications to the coronary arteries.^{30,103} Only in the latter setting is it expected to find histological abnormalities of the coronary arteries themselves.

The ventriculo-coronary fistulous connections can be single or multiple, and tend to communicate with the anterior interventricular or the right coronary arteries, less commonly to the circumflex artery.^{23,127} There is a wide spectrum of histopathological changes, found in both the intra- and extramural coronary arteries. These range from mild degrees of intimal and medial thickening, known as myointimal hyperplasia, to loss of normal morphology, with replacement of the arterial wall by fibrocellular tissue.³⁷ The process can cause severe distortion of the arterial structure, leading to endothelial irregularity, severe stenosis, or obliteration of the lumen.

Right Ventricular Dependent Coronary Arterial Circulation

As awareness of ventriculo-coronary arterial connections developed, so did an appreciation that surgical outcomes could be influenced by their presence and extent. Thus became established the concept of the right ventricular dependent coronary arterial circulation. In the normal situation, flow through the coronary arteries is mediated by the aortic diastolic pressure. Where there are ventriculo-coronary fistulous connections, exposure of the coronary arterial system to the high right ventricular pressures can result in stenoses and distortions, such that the aortic diastolic pressure is insufficient to drive flow into the arteries. The territory distal to the stenosis is then perfused retrogradely in systole by the right ventricle. Thus, the coronary arterial circulation is, at least, in part dependent on the right ventricle. Continued exposure of the arteries to the high pressures generated by the right ventricle then leads to further damage, thus compounding the problem. The consequence is that any intervention, resulting in decompression of the right ventricle, whether surgical or catheter, will lead to loss of coronary arterial perfusion, myocardial ischaemia, infarction, and possibly even death.² As summarised by Freedom and colleagues in their excellent review,² and listed in decreasing order of severity, the problems include:

- Atresia of the aortic orifices of both coronary arteries^{128–132}
- Atresia of the aortic orifice of the left coronary artery¹³³
- Proximal interruption or occlusion of the main stem of the left coronary artery, its anterior interventricular or circumflex branches, or the right coronary artery (Fig. 30-11), combined with fistulous communications from the right ventricle
- Important stenosis of the main stem of the left coronary artery, its anterior interventricular or circumflex branches, or the right coronary artery, in combination with fistulous communications from the right ventricle. Less severe abnormalities could also progress with time.
- Presence of a huge fistulous communication from the right ventricle to a coronary artery (Fig. 30-12). Although this situation is rare, decompression of the right ventricle in this setting would result in a massive steal, and hence result in coronary arterial insufficiency.

In two large series, the frequency of such a circulation has been documented at one-twentieth and one-tenth.^{23,60,72} Other studies have documented higher frequencies,^{92,93,127} but this may partly reflect the degree to which its presence is sought. There is also controversy as to how much myocardium must be jeopardised before the arrangement is termed a right ventricular dependent coronary arterial circulation.^{60,134–136} If it is to be of clinical value, of course, the right ventricular dependent coronary arterial circulation must be predicted prior to any attempted decompression.

CLINICAL DIAGNOSIS

Prenatal Diagnosis

Fetal echocardiography is now well-established, and has proved to be effective at detecting the lesion.¹⁷ Cases are usually detected because of an abnormal four-chamber view on echocardiography, but prenatal identification

Figure 30-11 This image shows a magnification of the base of the heart. Note that the right coronary artery (RCA) is atretic at its origin from the aorta. The territory of the anterior interventricular (intervent.) artery is fed primarily from the right ventricle by two prominent and ectatic fistulous communications. The pulmonary trunk (PT) is also grossly hypoplastic.

of tricuspid regurgitation, and even recognition of coronary arterial abnormalities, is now feasible.^{17,137–142} In the mainland of the United Kingdom, even by the early 1990s, two-fifths of all cases were diagnosed during fetal life.⁹ The proportion must now be even higher. This has changed the natural history of the disease, leading at least in the United

Kingdom to selective termination of pregnancy, fetal intervention, and planned delivery.

Postnatal Diagnosis

After birth, infants present with cyanosis in the neonatal period. The arterial duct is the sole source of flow of blood to the lungs, although this channel rarely remains widely patent for more than a few days. Very rarely, patients may be found with systemic-to-pulmonary collateral arteries,^{23,143–146} but usually, as soon as the duct narrows, arterial desaturation increases, and deep cyanosis results. Closure of the duct may be intermittent at first, and cyanosis may wax and wane. Infants with severe tricuspid regurgitation may also show signs of congestive heart failure.

PHYSICAL FINDINGS

The usual physical findings can be explained by the abnormal morphology. Cyanosis has already been discussed. Pulses and blood pressure are normal, since cardiac output is not impaired. The jugular venous pulse is hard to evaluate in newborns, and is not a useful diagnostic sign. Praecordial motion is normal, since a pure pressure overload of the right ventricle does not usually result in an exaggerated left parasternal lift. The second heart sound at the high left sternal border is soft and single, or is inaudible. The first heart sound is normal, and an ejection sound is not present. Several murmurs may be heard. The most common is a soft high-pitched continuous murmur at the high left sternal border. This murmur originates in the duct, and is usually quite subtle. Occasionally, it may be heard only intermittently, disappearing when the duct narrows and cyanosis deepens, and appearing again as the duct opens and cyanosis lightens. Some infants with pulmonary atresia have a soft high-pitched systolic murmur of tricuspid regurgitation at the low left sternal border. The presence of

Figure 30-12 In this heart, mural hypertrophy has obliterated the apex and narrowed significantly the outlet component. A, A fistulous communication is present in the anterior wall of the right ventricle. B, This feeds the ectatic anterior interventricular artery.

this murmur correlates strongly with a relatively large right ventricle,¹⁴⁷ but lack of a murmur of tricuspid regurgitation does not rule out a right ventricle of normal size. When there is severe tricuspid regurgitation, there is often a soft, medium-pitched, mid-diastolic murmur at the low left sternal border, representing increased tricuspid flow. Such a murmur is not heard in those with severe tricuspid stenosis alone, since there is little or no flow across such a valve in the presence of pulmonary atresia. Some infants with pulmonary atresia have no murmur. In this situation, the only indication of congenital cardiac disease on physical examination is the severe cyanosis.

INVESTIGATIONS

Electrocardiography

The electrocardiogram is usually abnormal, and reflects the abnormal morphology. The frontal plane axis is less rightward than normal, usually between 30 and 90 degrees. Most newborns have an adult praecordial pattern, rather than the usual right ventricular hypertrophy (Fig. 30-13). Less commonly, the pattern of right ventricular hypertrophy is present. It must be noted that the electrocardiographic patterns of right ventricular hypertrophy, or of left ventricular predominance, do not reliably predict right ventricular size. ST-T wave changes suggestive of myocardial ischaemia are occasionally present and may be related to the abnormal coronary arteries.¹²⁶ The tall peaked P waves of right atrial enlargement may be present.

Chest Radiography

There is no characteristic radiographic appearance. The abdominal organs are normally positioned, and the heart is left-sided. The bronchi are normally lateralised, and the

aortic arch is left sided. Pulmonary vascular markings are not increased, but the distinction between normal and decreased markings is difficult at best in the neonatal period, which is when most infants with pulmonary atresia present. The cardiac contour is not distinctive, and there is a wide range of cardiac size, from normal to wall-to-wall (Fig. 30-14). Although the very largest hearts occur when there is severe tricuspid regurgitation, the size of the heart is not a reliable predictor of the size of the right ventricular cavity.

Echocardiography

Cross sectional echocardiography is the diagnostic investigation of choice. As well as confirming the diagnosis, it is important also to document all the morphological features systematically, and then use the findings to determine the optimal strategy for treatment. In the first instance, the atrial arrangement should be confirmed. The right atrium will often be dilated. Any prominent venous valves should be noted. The oval foramen is usually widely patent before, but not always after, construction of a systemic-to-pulmonary shunt.¹⁴⁸ Next, the morphology of the tricuspid valve should be assessed, documenting any dysplasia or displacement of the leaflets (Fig. 30-15). The degree and velocity of regurgitation should be recorded (Fig. 30-16). The diameter of the valvar orifice should be measured, and converted to a z score using published nomograms.^{75,76} The measured orifice may not represent the effective orifice, particularly where there is limited opening due to tethering or raised filling pressures.

The right ventricle should be assessed to determine its overall size, and the degree of mural overgrowth (Fig. 30-17). A judgement should be made as to whether the cavity possesses all three of its components, or only one

Figure 30-13 Electrocardiogram demonstrating right atrial enlargement and left ventricular predominance that is abnormal for a term newborn infant.

Figure 30-14 Chest radiographs in two patients with pulmonary atresia and intact ventricular septum. A, Moderate cardiomegaly, right atrial enlargement, and decreased pulmonary vascular markings. B, Marked cardiomegaly in an infant with Ebstein's malformation of the tricuspid valve and severe tricuspid regurgitation.

Figure 30-15 This subcostal para-oblique view reveals a tripartite right ventricle with an imperforate pulmonary valve. There is minimal mural hypertrophy, but there is Ebstein's malformation of the tricuspid valve.

Figure 30-17 These two echocardiograms, both showing the four-chamber, illustrate the range in size of the right ventricular cavity. The upper panel shows a unipartite right ventricle, with considerable mural hypertrophy and obliteration of the cavity (*arrow*). The lower panel shows a tripartite right ventricle of near-normal size (*arrow*), with minimal mural hypertrophy. LV, left ventricle.

Figure 30-16 The image shows the continuous Doppler trace through the tricuspid valve of a baby with pulmonary atresia and intact ventricular septum. There is high velocity tricuspid regurgitation, with a peak velocity of more than 5 m/s, indicative of supra-systemic right ventricular pressures.

or two. In our experience, the right ventricular cavity may seem smaller echocardiographically than it appears angiographically, largely because the apical trabecular zone may seem completely obliterated when, in reality, there are intertrabecular spaces. The presence of tiny ventricular septal defects should be noted. An assessment of the patency of the infundibulum should be made, particularly from the subcostal para-oblique view. The atresia may be membranous (Fig. 30-18) or muscular depending on the extent of muscular mural hypertrophy. The presence of any forward or retrograde flow across the pulmonary valve should be assessed to exclude critical pulmonary stenosis

Figure 30-18 These images show an imperforate pulmonary valve suitable for balloon perforation. The left hand panel, seen from the parasternal short-axis view in ventricular diastole, demonstrates a normal appearance of the valve leaflets. The right hand panel shows the imperforate valve in systole, with excursion of the fused valvar leaflets. AV, aortic valve; PA, pulmonary trunk; PV, pulmonary valve; RV, right ventricle. (Reproduced with permission from Abrams DJR, Rigby ML, Daubeney PEF: Membranous pulmonary atresia treated by radiofrequency-assisted balloon pulmonary valvotomy. *Circulation* 2003; 107:e98–e99.)

or functional atresia. The presence of any fistulous communication to the coronary arteries should be sought.

The pulmonary trunk and branches should be measured to ascertain their size, and the source of flow of blood to the lungs determined. Normal pulmonary venous return should be confirmed. Structure and function of the left ventricle should be assessed, including regional abnormalities of mural motion.

Following such investigations, it should be possible to decide whether the long-term strategy is for biventricular as opposed to univentricular repair, and to plan the initial intervention.

Cardiac Catheterisation and Angiography

Despite the increased role of echocardiography, cardiac catheterisation and angiography may still be helpful in the evaluation of an infant with this lesion, particularly to assess the size of the right ventricle, and the presence and severity of fistulous communications. The usual approach is via the femoral vein, as it can be difficult to enter the right ventricle from the umbilical vein.¹⁴⁹ The latter approach can be used, however, for balloon atrial septostomy. Oximetry is not particularly helpful, except to show right-to-left shunting at atrial level. A step-up from right atrium to ventricle of more than 6% is said to be indicative of retrograde flow into the right ventricle from coronary arterial fistulous connections.¹⁴⁹ Mean right atrial pressure is usually slightly higher than left atrial, but a large gradient is not expected, since the oval foramen is usually large and widely patent. Right ventricular pressure is usually suprasystemic, although right ventricular pressure is low if tricuspid regurgitation is very severe (see Table 30-2). If the right ventricle is small, it may be entered only after repeated probing with an end-hole catheter.

The diagnosis will usually have already been made by echocardiography, but it can be confirmed by the right ventriculogram. Assessment of right ventricular size is far from simple in often bizarrely shaped right ventricles^{150,151} (Fig. 30-19). Stenosis or atresia of the infundibulum can be diagnosed. If an imperforate pulmonary valve is present, it may be seen moving to and fro at the top of a patent infundibulum. Tricuspid regurgitation can be roughly quantified, since catheter-induced regurgitation is usually

mild. Coronary arterial fistulous connections are also well-demonstrated by right ventriculography (see Fig. 30-19). Stenoses in, or interruption of, both right and left coronary arteries should be sought. If there is doubt about the coronary arterial anatomy or distribution after the right ventriculogram, then an injection should be performed in the aortic root. A left ventriculogram should also be performed, both for judging the relative right ventricular size, and to visualise the duct and the pulmonary trunk. Simultaneous injection into the aorta and into the right ventricle may show the extent of the gap between the right ventricular cavity and the pulmonary trunk in the presence of muscular atresia.¹²⁶ Cardiac catheterisation nowadays can be the prelude to an interventional approach to management.

Other Imaging Modalities

There has been rapid development of cardiac magnetic resonance and computerised tomographic imaging over the past decade. Both offer non-invasive alternatives to cardiac catheterisation and angiography, and may ultimately supplant such invasive techniques.¹⁵² They both provide excellent three-dimensional anatomical imaging of the cardiovascular system. Magnetic resonance provides assessment of flows, and does not require ionising radiation, but usually requires anaesthesia in the newborn. Computerised tomography offers fast acquisition, and perhaps better resolution, but does require ionising radiation.

HAEMODYNAMICS AND PHYSIOLOGY

Systemic venous return to the right atrium is normal (see Fig. 30-1). The flow prenatally was to the left atrium through a patent oval foramen, and to the left heart, continuing retrogradely via the arterial duct into the pulmonary arteries. This continues after birth until closure of the duct. The increased pulmonary venous return to the left atrium may reduce the size of the foramen, which is particularly important after construction of a systemic-to-pulmonary arterial shunt, since the restrictive foramen may need to be enlarged using balloon atrial septostomy.¹⁴⁸

When the tricuspid valve is hypoplastic, its opening may be limited anatomically, but also functionally by high filling pressures. The right ventricular pressure will then be

Figure 30-19 The angiograms show the range of morphology to be seen in pulmonary atresia with intact ventricular septum. A, Right ventricular angiogram showing a dilated and thin-walled right ventricle and atrium, with severe tricuspid regurgitation, in the setting of an imperforate pulmonary valve, seen in the frontal projection. B, A so-called tripartite right ventricle, seen in lateral view. C, Frontal projection showing the so-called bipartite arrangement, in this instance with an imperforate pulmonary valve and some fistulous connections with the coronary arteries. D, Lateral projection showing the tiny, so-called unipartite, arrangement with muscular atresia and fistulous communications filling the coronary arteries.

supra-systemic. Egress of blood from the right ventricle is via low volume, but high velocity, tricuspid regurgitation and/or ventriculo-coronary arterial connections into the aorta during systole. There can be retrograde filling of the right ventricle from the coronary arteries during diastole. Right ventricular systolic pressures can cause high shear stress to the coronary arterial walls, leading to stenoses and the right ventricular dependent coronary arterial circulation. In these circumstances, alteration of the balance of right ventricular and aortic diastolic pressures can lead to myocardial infarction. Hence, right ventricular decompression should be avoided whenever there is a right ventricular dependent coronary arterial circulation. Caution should be undertaken when creating a systemic-to-pulmonary arterial shunt, taking care to ligate the arterial duct so as to prevent any disastrous falls in the diastolic blood pressures.¹⁵³

Left ventricular function can also be affected,^{44,112,114} and it has been suggested that the left ventricle may ultimately be the limiting factor in this disease.¹¹⁴ Long-term

haemodynamic effects usually reflect residual lesions. Biventricular circulation may be complicated by the long-term effects of residual pulmonary stenosis, regurgitation, and tricuspid regurgitation. The functionally univentricular circulation may be complicated by the long-term effects of high venous pressure, right atrial dilation, and coronary arterial stenoses. Incompletely separated circulations may suffer the additional long-term effects of cyanosis.¹⁵²

THERAPEUTIC OPTIONS

Historical Perspective

Already by the mid 1950s, pulmonary valvotomy had been proposed as an appropriate treatment when the right ventricle was of good size.^{78,154} It was also suggested that a systemic-to-pulmonary arterial shunt be performed when the right ventricle was small.¹⁵⁵ The first reports of successful surgery came from the Mayo Clinic, the University of Minnesota, and the Henry Ford Hospital.¹⁵⁵⁻¹⁵⁷

The combination of repair of the right ventricular outflow tract and construction of a systemic-to-pulmonary arterial shunt was first reported in 1971.¹⁵⁸ These techniques are still the mainstay of surgical interventions today, but the indications for each have been considerably refined as our knowledge of the morphological complexities have grown.

Successful percutaneous perforation of the atretic pulmonary valve with a catheter was first reported in 1991, using either a guide-wire,¹⁵⁹ laser energy,^{160,161} or radio-frequency energy.^{162,163} This approach has now become the treatment of choice in many centres for those patients with a good-sized right ventricle and an atretic valvar membrane.

Contemporary Approaches

Fetal Intervention

Fetal intervention is now a reality, although its rate of success at present is low, and it must still be considered an experimental technique.^{164–167} Its role in management is still being explored.

Postnatal Intervention

Since the lesion is duct-dependent, an infusion of prostaglandin is commenced after diagnosis, and the baby transferred to a cardiac unit. The investigations discussed above are performed to identify the unique constellation of morphological features. The long-term goal of intervention is to separate the pulmonary and systemic circulations. The investigations, therefore, are directed to ascertain whether this can be achieved by creating either biventricular or functionally univentricular circulations. Different strategies are adopted depending on whether it is deemed likely that one or other repair is possible (Table 30-3).

For patients with a diminutive right ventricle, which would never support the pulmonary circulation, the ultimate aim would be a modified Fontan-type circulation in which systemic venous return was directly to the pulmonary arteries. This strategy would commence initially with consideration of a balloon atrial septostomy. Unless the oval foramen is substantial, a septostomy is recommended, the more so since, after construction of a systemic-to-pulmonary arterial shunt, the foramen can become restrictive, either

immediately or over time, with disastrous outcome.¹⁴⁸ Following septostomy, the shunt is constructed,¹⁵⁵ usually a left- or right-sided modified Blalock-Taussig shunt. The next procedure, performed at the age of 3 to 24 months, would be a bidirectional cavopulmonary anastomosis. The Fontan circulation would then be completed at the age of 24 to 60 months.

Surgical management of the right ventricle of good size is aimed at achieving a biventricular circulation, in which the right ventricle can pump blood to the lungs (see Table 30-3). This needs consideration of the size and function of the tricuspid valve and right ventricle. Where there is a good-sized right ventricle and infundibulum, then a pulmonary valvotomy or valvectomy can be performed,⁷⁸ with or without cardiopulmonary bypass, and with or without creation of a systemic-to-pulmonary arterial shunt as an adjuvant to pulmonary flow. Where there is a less substantial infundibulum, a transjunctional patch can be performed with a limited ventriculotomy, or alternatively a pulmonary homograft inserted. Where there is doubt about whether the right ventricle alone can provide enough forward flow to the pulmonary arteries, a transjunctional patch could be combined with a systemic-to-pulmonary arterial shunt.¹⁶⁸ Ultimately, as the right ventricular hypertrophy regresses and compliance improves, the shunt can be closed. In those in whom this initial approach failed to lead to growth of the right ventricle, the right ventricular hypertrophy can be debulked, combined with repair of the tricuspid and pulmonary valves as required.¹⁶⁹

Where forward flow through a repaired right ventricular outflow is insufficient to prevent cyanosis, a bidirectional cavopulmonary anastomosis can also be created. This has been termed the one and a half ventricle repair, and may be a suitable long-term palliation for some bipartite right ventricles.¹⁷⁰ Variations of the above strategies have been described, whereby continuity is maintained between the right atrium and the superior caval vein.¹⁷¹

For patients with a right ventricular dependent coronary arterial circulation, other procedures have been proposed, such as closure of the tricuspid valve at the same time as concurrent procedures,^{172–174} or construction of a conduit from the aorta to the right ventricle.^{175–177} More recently, it has been shown that a successful outcome can be achieved

TABLE 30-3

OPTIONS FOR MANAGEMENT FOR EACH INITIAL STRATEGY

Initial Strategy			Procedures		
Biventricular repair	Catheter		Wire perforation + balloon dilation		
			Laser perforation + balloon dilation		
			Radio-frequency perforation + balloon dilation		
	Surgery		Pulmonary valvotomy		
			Pulmonary valvectomy		
Transjunctional patch					
<i>Any of above with systemic to pulmonary shunt</i>			Monocusp homograft		
Univentricular repair	Balloon atrial septostomy	Surgery	Systemic-to-pulmonary shunt	Superior cavopulmonary anastomosis	Total cavopulmonary connection

From Daubeney PEF: Pulmonary atresia with intact ventricular septum. In Gatzoulis MA, Webb GD, Daubeney PEF (eds): *Diagnosis and Management of Adult Congenital Heart Disease*. London: Churchill Livingstone, 2003, pp 339–347

by following a staged palliation directed towards completion of a fenestrated Fontan circulation.¹⁷⁸

Various controversies still remain. Whether a procedure on the right ventricular outflow tract should be performed in all cases, even when the right ventricle is diminutive, excepting cases of right ventricular dependence, is unresolved. Whether all such procedures should also be accompanied by construction of a systemic-to-pulmonary arterial shunt is also not clear. The need for a transjunctional patch needs clarification. Lastly, it needs to be resolved whether an early procedure on the right ventricular outflow tract is required to optimise right ventricular growth.

Catheter Management

The majority of patients have membranous rather than muscular atresia, with a patent infundibulum, and often a well-developed right ventricular cavity (see Fig. 30-18). Diverse surgical strategies have been recommended for this group, such as neonatal valvotomy, valvectomy, and transjunctional patching with or without concomitant placement of a systemic-to-pulmonary shunt. Since the early 1990s, there has been an increasing trend toward perforation of the atretic pulmonary valve as the primary procedure.^{67,68,74,148,159–163,179–191} In some cases, the arterial duct is also stented.¹⁸⁸ As technical success in perforating the atretic valve has increased, the place of this technique in the management of those with good-sized right ventricles has been hotly debated. This issue remains unanswered, but from a pragmatic stance, the choice of surgical versus catheter valvotomy in an individual institution should be determined on the basis of the technique which causes the least mortality and morbidity.

Outcomes of Intervention

After hypoplastic left heart syndrome, this lesion has proved to be one of the most disappointing to treat. Improvement in outcome over the past 20 years has been extremely slow (Table 30-4), with occasional exceptions.⁹⁰ In Figure 30-20, survival curves are shown as drawn from the population-based study conducted in the United Kingdom and Eire, stratified for initial procedure and the partite state of the right ventricle.^{9,148}

Why this lesion should have such a poor outcome is not well-identified, and optimal strategies for treatment remain to be elucidated. The largest four studies have identified risk factors for poor outcome. These include factors relating to the small size of the right ventricle, dilated

right ventricular size, low birth weight and prematurity, presence of right ventricular-to-coronary artery fistulous connections, and a right ventricular dependent coronary arterial circulation.^{60,66,72,84,92,148} As more is learnt about adverse risk factors, clinicians are tailoring their approach, for example by not decompressing right ventricles where there is thought to be a right ventricular dependent arterial circulation. Freedom and colleagues stated in 2005 that 'ventriculo-coronary connections, and a right ventricular dependent coronary circulation, an important risk factor in our (their) earlier surgical experience,^{84,192} therefore, had been effectively neutralised by the introduction of the functionally univentricular palliation'.²

Catheter perforation of the imperforate pulmonary valve is now a well-established technique for primary intervention. It accounted for three-fifths of all valvotomies performed without concomitant construction of a shunt in the study carried out in the United Kingdom and Eire.¹⁴⁸ When analysed on the basis of intention to treat, survival was similar between those treated at catheterisation or surgically. A recent report notes ongoing technical improvement, with a mortality of only 10%.¹⁸⁸ Successful perforation of the atretic pulmonary valve is not guaranteed, but rates of success recently published range from 85 to 90%.^{185–187}

LONG-TERM OUTCOME

Survivors are now reaching adulthood, but their numbers are small due to the rarity of the disease, and high mortality in previous eras. Little data is available about long-term survival and functional state. Mortality tends to occur in the first 6 months of life and the survival curves then flatten (see Fig. 30-20).^{60,148,193} One study documented survival after 14 years following biventricular repair of 86%.¹⁹³ Of the patients, one-fifth had late arrhythmias, and right atrial dilation was found in all patients. At the current time, prediction of longer-term outcome for a biventricular repair can only be made by drawing parallels with other diseases, such as those who have undergone definitive repair of pulmonary stenosis and tetralogy of Fallot (see Chapters 43 and 36).

For those embarking down the route toward construction of the Fontan circulation, mortality tends to occur early in childhood, often within a few months of the initial procedure.^{60,194} There is an ongoing mortality hazard but the early data available indicates that the influence of coronary arterial abnormalities may be less than predicted.^{194,195}

*Uses most recent era data from the study.

†Estimate of mortality at 1 and 5 years.

‡Survival of those who underwent a procedure.

Figure 30-20 The graphs show the Kaplan-Meier survival curves for subgroups of patients with pulmonary atresia and intact ventricular septum. (Data from the UK and Ireland population-based study.¹⁴⁸)

In the future it will be interesting to discover how persisting right ventricular hypertension, and coronary arterial fistulous connections, influence long-term outcome.

Recommendations for Long-term Follow-up

For those with a biventricular repair and minimal residual haemodynamic lesions, patients should be seen every 1 to 3 years by a cardiologist. Where there are significant residual lesions, follow-up should be yearly by an adult congenital cardiologist. Similarly, patients with mixed or functionally univentricular circulations warrant follow-up in a tertiary centre. For patients with venous shunts, or the Fontan circulation, strong consideration should be given to full anticoagulation, particularly if there is suspicion of coronary arterial abnormalities.

Exercise limitations need to be reviewed on an individual basis, depending on type of surgical route followed, the underlying haemodynamics, and the overall state of the patient. Endocarditis prophylaxis is not required but high levels of dental hygiene are recommended.

At each visit, it is essential to assess residual morphological lesions. Following a biventricular repair, the patient should be pink, with normal volume pulses, albeit that the jugular venous pulse may be elevated, and the right ventricular impulse increased. There will usually be a normal first heart sound with single second, which may be split if a homograft has been inserted. Murmurs of residual pulmonary stenosis, regurgitation, and tricuspid regurgitation may be evident. Hepatomegaly may be present. Indeed, if tricuspid regurgitation is severe, the liver may be pulsatile. Patients are prone to atrial arrhythmia.

Following a Fontan procedure, the patient should be pink, with saturations in the 90s, brachial pulses may be absent following previous arterial shunt procedures, the jugular venous pulse will be greatly elevated, and may only be visible on sitting up. There will be a single heart second. There may be a murmur from tricuspid regurgitation or a systolic murmur caused by blood flow from a high pressured right ventricle into a coronary arterial fistula. Hepatic congestion may be evident.

For patients with a mixed circulation, the patient will be cyanosed with clubbing, erythrocytosis, possible continuous murmurs due to patent systemic shunts, and may have features of either circulation described above.

Chest radiography will often show an increased cardiothoracic ratio with, in particular, a dilated right atrial contour. In patients with severe tricuspid regurgitation, the right ventricle may also be dilated. In those with a mixed circulation, there may be pulmonary oligoemia.

The electrocardiogram may show the presence of arrhythmias, atrial or ventricular. There is often P pulmonale due to right atrial dilatation. The QRS axis usually shows left ventricular dominance.

Echocardiography should be used to document systematically and sequentially all the morphological features discussed at the beginning of this chapter. Residual lesions such as atrial septal defects and patent systemic shunts should be sought. For those with a biventricular circulation, the presence and degree of tricuspid regurgitation, pulmonary regurgitation, and stenosis should be documented. The size and z score of the tricuspid valve should be documented. For those with a Fontan circulation, careful assessment of the anastomoses is needed as well as assessment of left ventricular function, mitral regurgitation and the presence of right atrial thrombus. Imaging of the coronary artery origins and their size may suggest significant fistulous communications.

Cardiac catheterisation may be required to assess the haemodynamics of the Fontan circuit. Coronary arteriography is essential as stenoses and interruptions may play a significant part in the prognosis. Assessment of the pulmonary arterial anatomy is important, as the patient may have had a systemic-to-pulmonary arterial shunt in the past, with pulmonary arterial distortion. In contrast to pulmonary atresia with tetralogy of Fallot, native stenoses or hypoplasia of the pulmonary arteries are relatively uncommon. Baffle leaks should be sought in those with a Fontan circulation.

Cardiac magnetic imaging and computer tomography may supplant catheterisation as a means of non-invasive assessment of the range of morphological lesions found in this condition. They give excellent anatomic and, in the case of magnetic imaging, excellent functional information.

Nuclear imaging conveys important information about myocardial perfusion and ischaemia, particularly for those patients with significant coronary artery lesions although abnormal anatomy imposes technical challenges.

Implications in Adult Life

Physiological

Many patients with this condition are reaching adulthood. Their well-being in adult life depends on the cumulative effect of complications throughout their life, be they cardiac and non-cardiac, reasonable cardiac function, and avoidance of residual lesions.¹⁵²

For those with biventricular or one and a half ventricle repairs, residual lesions comprise pulmonary stenosis, regurgitation, and tricuspid regurgitation. These can lead to atrial and ventricular arrhythmias, syncope, sudden death, reduced exercise tolerance, fatigability, and angina. For those with a functionally univentricular repair, such as a total cavopulmonary connection or Fontan-type

circulation, residual lesions comprise right atrial dilation, coronary arterial stenoses, high systemic venous pressures, and systemic-to-pulmonary arterial and venous collateralisation. These can lead to atrial and ventricular arrhythmias, sudden death, thrombo-embolism, right pulmonary venous occlusion, angina, left ventricular dysfunction, protein-losing enteropathy, hepatic dysfunction and cyanosis. For those with incompletely separated circulations, there is common mixing of systemic and pulmonary circulations leading to cyanosis, erythrocytosis, thrombo-embolism, fatigability, and arrhythmias.

Contraception and Pregnancy

Pre-pregnancy counseling is essential. This should include contraceptive advice tailored to the individual cardiac structure and function. Those with a good biventricular repair should be suitable for all forms of contraception. Those with ongoing cyanosis or a Fontan-type circulation should avoid the combined contraceptive pill. Detailed advice is beyond the scope of this book but is thoroughly covered elsewhere.¹⁹⁶

Biventricular Repair with Residual Pulmonary

Stenosis or Regurgitation

The increased haemodynamic load of pregnancy may precipitate right heart failure, atrial arrhythmias, or tricuspid regurgitation. Balloon dilation can be performed during pregnancy, preferably after organogenesis, although it is better to treat before conception.

Functionally Univentricular Circulation

There are increased risks of systemic venous congestion, deterioration in ventricular function, atrial arrhythmias, thrombo-embolism, and paradoxical embolisation if there is a fenestration in the atrial baffle. Successful pregnancy is possible, however, with meticulous cardiac and obstetric planning and supervision. If anticoagulation is required additional risks to the fetus are involved.

Mixed Circulations with Cyanosis

There is an increased risk of maternal cardiovascular complications, prematurity and fetal death, particularly when baseline maternal resting saturations are less than 85%.

All patients should have cardiological counselling prior to conception, and follow-up by an adult congenital cardiologist and a high-risk obstetrician during pregnancy and the peripartum. Fetal echocardiography is recommended.

Insurance and Employment

This will depend on the original diagnosis and residual lesions. There may not be specific stratification of risk for this particular lesion, and parallels from other lesions, such as pulmonary stenosis, tetralogy of Fallot, and patients with Fontan-type circulations, may have to be taken. Employability will depend on exercise ability, avoidance of complications, and ongoing particularly neurological morbidity. Employment would need to be tailored to individual needs. Detailed discussion of these topics is beyond the scope of this chapter, albeit that they are thoroughly covered elsewhere.¹⁹⁷

Very good review of the disease in adult life including outcome, complications, and outpatient assessment and management.

Other Forms of Functionally Univentricular Hearts

DANIEL J. PENNY and ROBERT H. ANDERSON

The terms univentricular and single have proven to be amongst the most controversial adjectives used to describe some of the most complex congenital malformations of the heart. Since the mid-1990s, light has begun to emerge at the end of the tunnel for those who have attempted to provide a logical framework for the description of these complex conditions. This has stemmed from the realisation by clinicians that the decision underscoring the eventual presence or absence of a functionally univentricular arrangement is whether treatment of the individual patient is to proceed towards creation of biventricular circulations, or rather to establish the Fontan circuit, which of necessity produces circulatory patterns supported by only one ventricle, even if two chambers are unequivocally present within the ventricular mass.¹ For example, in a patient with critical aortic stenosis, the clinician will seek to determine whether the best option for the patient is to seek to achieve biventricular repair or opt for univentricular palliation, recognising that such a patient possesses both morphologically right and left ventricles. There are many patients, therefore, including those with hypoplastic left heart syndrome, those having pulmonary atresia with intact ventricular septum, as well as some with straddling of the atrioventricular valves or double outlet ventricle, for whom the clinician may choose a mode of treatment culminating in production of a functionally univentricular heart. All these conditions have either already been considered in other chapters—hypoplasia of the left heart in Chapter 29 and pulmonary atresia with intact septum in Chapter 30, or will be considered in chapters to follow, specifically straddling atrioventricular valves in Chapter 40 and double outlet ventricles in Chapter 33. In this chapter, we are concerned with describing the underlying morphology, and clinical diagnosis, of the lesions that produced most controversy previously in the definition of single ventricles or univentricular hearts, namely, double inlet ventricle and atrioventricular valvar atresia. In the next chapter, having established the principles for analysis of these problematic lesions, we will discuss the long-term options for all those patients having the functionally univentricular arrangements.

PHILOSOPHICAL CONSIDERATIONS

When considered from the stance of cardiac morphology, hearts having a solitary chamber within the ventricular mass, and hence truly being univentricular, are extremely rare. They do exist, and when found, they most usually exhibit double inlet to a chamber having indeterminate apical trabeculations, and in which the only septal

structure present is the muscular outlet septum (Fig. 31-1). The essence of such hearts is that the atrial chambers are joined to the solitary ventricle. It is possible, of course, that such an arrangement, with the atrial chambers connected exclusively to a solitary ventricle of indeterminate morphology, can be found when either the right- or left-sided atrioventricular connection is absent, but such hearts are exceedingly rare. It was recognition of the significance of such a univentricular arrangement of the atrioventricular junctions, nonetheless, that clarified the polemics underscoring the previous disagreements.^{2,3} Thus, subsequent to the important study that had appeared in 1964,⁴ it had become accepted⁵ that the criterion for definition of a single ventricle was the presence of double inlet. Those accepting this concept, however, ignored that fact that, when the morphology of the small ventricle in patients with tricuspid atresia was compared to that of the same chamber in those with double inlet left ventricle, the comparison being made in the setting of lesions with the same ventriculo-arterial connections, then the small ventricles were essentially indistinguishable⁶ (compare Figs. 31-2 and 31-3). This is because, in the setting of either the commonest form of tricuspid atresia or in those with double inlet left ventricle, the big ventricle is of left ventricular morphology, while the small ventricle is an incomplete right ventricle, lacking totally its inlet component (Figs. 31-4 and 31-5). Recognition of this feature led to the realisation that, in both these anomalies, it was the atrioventricular

Figure 31-1 This heart has a truly solitary ventricle, with exceedingly coarse apical trabeculations of indeterminate morphology. There is double inlet to, and double outlet from, the solitary ventricle. This is the anatomical univentricular heart.

Figure 31-2 The heart is photographed from the front to show the morphology of the antero-superior ventricular chamber, which lacks its inlet, but has an apical component of right ventricular (RV) morphology. The ventricle gives rise to the pulmonary trunk, whilst the aorta arises from the dominant ventricle, which also receives both atrioventricular valves. This is an example of the so-called Holmes heart. VSD, ventricular septal defect.

Figure 31-3 This heart is photographed in comparable fashion to the one shown in Figure 31-2. In this instance, however, there is tricuspid atresia due to absence of the right atrioventricular connection. There is no fundamental difference in the structure of the morphologically right ventricle (RV) from that shown in Figure 31-2. Both ventricles are incomplete because they lack their inlet components. VSD, ventricular septal defect.

Figure 31-4 The heart is sectioned to replicate the parasternal long-axis section. It shows the structure of double inlet left ventricle (LV) with discordant ventriculo-arterial connections. Note the dominant left ventricle and the antero-superiorly located incomplete right ventricle (RV). LAVV, left atrioventricular valve; RAVV, right atrioventricular valve.

connection, rather than the ventricular mass, which was univentricular.^{2,3} This, in turn, led to the realisation that all patients with congenitally malformed hearts, with one small exception, could be divided into those with biventricular atrioventricular connections, this group made up of those with concordant, discordant, and ambiguous and mixed atrioventricular connections, and those unified because the atria are joined to only one ventricle, either because both atria are committed to the same ventricle, in other words those with double inlet ventricle, or because one of the connections between the atria and the ventricular mass is completely absent, producing the commonest form of atrioventricular valvar atresia. The very small third group of patients is made up of those with absent atrioventricular connection and straddling and overriding of the solitary atrioventricular valve,⁷ this combination producing a uniatral but biventricular connection (Fig. 31-6). In all those with univentricular atrioventricular connections (Fig. 31-7), apart from the very small minority having solitary and indeterminate ventricles, there is a second ventricle within the ventricular mass that, of necessity, is incomplete and rudimentary. Among these patients, three additional groups stand out as requiring separate description, namely, those with double inlet, those with absence of the right atrioventricular connection, and those with absence of the left atrioventricular connection. It is patients with hearts of this type we describe in this chapter, along with their close cousins with imperforate atrioventricular valves, the latter also producing unequivocal atrioventricular valvar atresia.

MORPHOLOGY

As we have already explained in Chapter 1, there are three possible junctional arrangements producing anatomical univentricular atrioventricular connections (see Fig. 32-7). The first is when the cavities of right- and left-sided atrial chambers are connected directly to the same ventricle. This

Figure 31-5 This example of tricuspid atresia is sectioned to replicate the parasternal long-axis section. As with the heart shown in Figure 31-4 with double inlet left ventricle, there is a dominant left ventricle, and an incomplete right ventricle located antero-superiorly.

Figure 31-6 The heart illustrated shows a rare variant of tricuspid atresia due to absence of the right atrioventricular connection (yellow dotted lines), but with straddling and overriding of the left atrioventricular valve (arrows). Because the valve is supported by both ventricles but takes its origin only from the left atrium, the resulting atrioventricular connection is uniaxial but biventricular. Morph. LV, morphologically left ventricle.

Figure 31-7 The cartoon shows the segmental combinations producing a univentricular atrioventricular connection. The middle row shows the possible connections, which can co-exist with any atrial arrangement, as shown in the top row. Any of the atrioventricular connections can also exist with any of the three ventricular morphologies shown in the bottom row, although they are illustrated only with double inlet ventricle. Further variations are possible at the ventriculo-arterial level, and because of associated malformations.

is called double inlet atrioventricular connection, irrespective of whether the atrioventricular junctions are guarded by two atrioventricular valves or a common valve. The other two arrangements exist when one atrioventricular connection is absent, giving absence of the right-sided and left-sided atrioventricular connections, respectively. All of these patterns at the atrioventricular junction can be found in patients having usually arranged, mirror-imaged or isomeric atrial appendages. Each type of atrioventricular connection can also be found with the atriums connected to a dominant right ventricle, a dominant left ventricle, or rarely, to a solitary and morphologically indeterminate ventricle (see Fig. 32-1).

Atrioventricular Connections

The feature underpinning the anatomy of absent right atrioventricular connection is emphasised when patients having an imperforate tricuspid valve (Fig. 31-8) are compared with those having complete absence of the right atrioventricular connection (Fig. 31-9). Although these two anatomical entities produce the same physiological effect, their morphology is totally different. An imperforate valve can only be formed in the setting of a discrete atrioventricular junction. With this arrangement, the parietal myocardium of the atrium is continuous with the parietal ventricular wall. Hence, the cavities of the atrium and the underlying ventricle are in potential communication. When the atrioventricular connection is absent, this is not the case. The parietal walls of the right atrium and of the ventricle have no direct continuity, but instead they meet

Figure 31-8 The heart, with imperforate right atrioventricular valve producing tricuspid atresia, has concordant atrioventricular connections. This is a rare variant of tricuspid atresia, in this instance co-existing with pulmonary atresia in the setting of intact ventricular septum.

Figure 31-9 This heart, to be compared with the one shown in Figure 31-8, and also sectioned to replicate the echocardiographic four-chamber cut, shows that the essence of classical tricuspid atresia is complete absence of the right atrioventricular connection (green dotted lines).

Figure 31-10 The image is a close-up of a section through the dimple in a heart with classical tricuspid atresia. The green dotted lines show the cavity of the incomplete right ventricle. As shown by the probe, the dimple points into the cavity of the dominant left ventricle. It is the atrioventricular component of the membranous septum.

at the central fibrous body, with the fibro-fatty tissues of the atrioventricular groove filling the space between the adjacent layers of atrial and ventricular myocardium. The atrium has a complete muscular floor, which is the lateral wall of the appendage. A muscular dimple is frequently seen antero-superior to the orifice of the coronary sinus. This is often, incorrectly, presumed to represent the site of the right atrioventricular orifice. Sectioning through the dimple shows that it overlies the atrioventricular membranous component of the central fibrous body, and points to the outflow tract of the morphologically left ventricle (Fig. 31-10). A similar distinction needs to be made between

Figure 31-11 This heart, a variant of hypoplastic left heart syndrome, has been sectioned in four-chamber fashion. It shows complete absence of the left atrioventricular connection (*green dotted lines*), with the incomplete left ventricle in inferior and left-sided position.

absence of the left atrioventricular connection and biven-tricular atrioventricular connections with an imperforate mitral valve. When the left connection is absent, the fibro-fatty tissue of the left atrioventricular groove separates completely the muscular floor of the left atrium from the underlying ventricular myocardium (Fig. 31-11).

When analyzing the morphology of the atrioventricular junctions in hearts with double inlet ventricle, it should be noted that double inlet exists because both atrial vestibules connect to the same ventricle, irrespective of whether the right- and left-sided atrioventricular junctions are guarded by two separate atrioventricular valves or a common valve (Figs. 31-12 and 31-13). And, as we have already shown in Figure 31-7, double inlet ventricle can occur with any atrial arrangement. The usual arrangement is the most common, but isomerism of the right atrial appendages is by no means rare, particularly when there is double inlet right ventricle. Common atrioventricular valves are also particularly frequent when there is right isomerism.

Abnormalities of the atrioventricular valves are frequent, in particular in hearts with double inlet left ventricle. In this setting, when there are separate right and left atrio-ventricular valves, both usually resemble mitral valves, lacking any tethering to the antero-superiorly located ventricular septum. They are also usually supported by separate papillary muscles, but often separated on the inferior ventricular wall by a prominent ridge. The two valves can also share papillary muscles, with no plane of cleavage between them, this feature ruling out the potential for ventricular septation. Where one or the other arterial valve is connected to the left ventricle, both atrioventricular valves are usually in continuity with it, although either, or rarely both, may be separated from it by persistence of the ventriculo-infundibular fold. Either the right or the left atrioventricular valve may be imperforate or stenotic, or may straddle or override the ventricular septum. In the setting of overriding and straddling atrioventricular valves, as we will explain in greater detail in Chapter 33, providing more than half of the vestibule of the overriding

Figure 31-12 This heart has double inlet right ventricle (RV), with the right and left-sided atrioventricular junctions guarded by a common atrioventricular valve (*bracket*). Note that the incomplete left ventricle (LV) is positioned inferiorly and to the left, but with the ventricular septum extending to the crux.

Figure 31-13 This heart, sectioned to replicate the four-chamber section, shows double inlet to a dominant right ventricle with separate right and left atrioventricular valves. The incomplete left ventricle, not seen, is positioned inferiorly and to the left.

junction is connected to the dominant ventricle, we continue to categorise the connection as double inlet. In patients with absence of either the right or left atrioventricular connection, the remaining atrioventricular valve may straddle, producing the rare uniatrial and biventricular connection (see Fig. 31-6).

The Ventricles

In almost all hearts in which there is a univentricular atrioventricular connection, there are complementary ventricles present of left and right ventricular morphology, separated by the apical muscular ventricular septum (see Figs. 31-4 and 31-12). In the majority of patients with absent right atrioventricular connection, this being the arrangement producing classical tricuspid atresia, the left atrium is connected to a dominant left ventricle (see Fig. 31-9). In these hearts, and indeed in all those having a dominant left ventricle, the incomplete right ventricle is carried on the antero-superior shoulder of the ventricular mass, almost always with its trabecular component to the right. In hearts with double inlet left ventricle, when the incomplete right ventricle is again found in an antero-superior position, the apical trabecular component can be either right- or left-sided, or directly anterior. In all situations in which the left ventricle is dominant, unlike in hearts with biventricular atrioventricular connections, the hypoplastic apical muscular ventricular septum does not extend to the crux.

When it is the right ventricle which is dominant, the incomplete left ventricle is located in postero-inferior position, usually to the left of the dominant ventricle, but rarely to the right. In both of these settings, the hypoplastic ventricular septum does extend to the crux. Absence of the left atrioventricular connection with the right atrium connected to a dominant right ventricle produces one of the frequent variants of hypoplastic left heart syndrome (see Fig. 31-11). Absence of the right atrioventricular connection can also rarely be found when the left atrium is connected to a dominant right ventricle, and again the incomplete left ventricle will usually be located postero-inferiorly, this arrangement being found most frequently in association with straddling and overriding of the left atrioventricular valve (Fig. 31-14).

Ventriculo-arterial Connections

Any type of ventriculo-arterial connection must be anticipated to exist in the setting of the univentricular atrioventricular connection, as long as they are anatomically feasible. Should there be a solitary ventricle of indeterminate morphology, however, the only possibilities are double outlet from the solitary ventricle (see Fig. 31-1), or one of the variants of single outlet, usually pulmonary or aortic atresia rather than common arterial trunk. When the left ventricle is dominant, then concordant ventriculo-arterial connections are the rule in the setting of tricuspid atresia, and discordant connections are typically found when there is double inlet. When it is the left atrioventricular connection which is absent, then it is most usual to find aortic atresia with origin of the pulmonary trunk from the right ventricle, this being one of the frequent variants of hypoplastic left heart syndrome (see Fig. 31-11 and Chapter 29). As emphasised, however, any connection must be anticipated to exist, and concordant ventriculo-arterial connections are by no means rare when there is double inlet left ventricle, this combination producing the so-called Holmes heart (see Fig. 31-2). Should there be double inlet to, and double outlet from, the dominant left ventricle, then the incomplete right ventricle is represented only by its apical trabecular component, which continues to be positioned antero-superiorly, albeit either to the right or the left. When it is the right ventricle that is dominant, then most usually there is also double outlet from the right ventricle. The incomplete left ventricle is then represented only by its apical trabecular component, positioned postero-inferiorly, and usually to the left. Concordant ventriculo-arterial connections can be found, most usually when there is a common atrioventricular valve, but other connections are rare.

Figure 31-14 These images show a heart with absence of the right atrioventricular connection (A), but with straddling and overriding of the left atrioventricular valve, viewed from the left atrium and from behind in panel B. As with the heart shown in Figure 31-6, this produces a uniaxial but biventricular connection, but unlike the heart shown in Figure 31-6, in this heart there is left hand ventricular topology. The morphologically left ventricle is positioned inferiorly and to the right (arrow in B).

Interventricular Communication

In patients with a dominant left ventricle, irrespective of the precise atrioventricular connection, the hole between the ventricles is almost always completely surrounded by muscle, being located between the apical and outlet components of the ventricular septum. This hole has been described in various ways over the years, being called a bulboventricular foramen, an outlet foramen, or a ventricular septal defect. It is an integral part of one of the circulations when the ventriculo-arterial connections are concordant or discordant. It has a tendency to become obstructive with time (see Figs. 31-2 and 31-3). In the setting of discordant ventriculo-arterial connections, such a reduction in the size produces subaortic obstruction (Fig. 31-15), but results in subpulmonary obstruction when it is the pulmonary trunk which arises from the incomplete right ventricle. It is well established that the defect can decrease markedly in size, albeit that a purported causal association with banding of the pulmonary trunk⁸ remains to be proved.

The interventricular communication in hearts with dominant right ventricles is usually perimembranous, since the hypoplastic septum extends to the crux in this setting, and the defect is directly related to the atrioventricular valve or valves. In most instances when the right ventricle is dominant, both arterial trunks also arise from the dominant right ventricle, and the left ventricle is represented only by its apical trabecular component, albeit often in association with minimal straddling of the left atrioventricular

valve (Fig. 31-16). In this situation, the interventricular communication is not an integral part of the circulation to one or other outflow tract, as it usually is when the left ventricle is dominant, and hence the morphology of the interventricular communication is of less clinical significance.

Associated Malformations

The interventricular communication is part and parcel of the morphology of hearts having dominant right or left ventricles, and does not exist in those with solitary and indeterminate ventricles. In those with dominant left ventricles, it is the size of the interventricular communication that is the major determinant of clinical presentation, recognising that this feature is, of course, also dependent on the ventriculo-arterial connections. The presence of other associated malformations can then further modify the clinical presentation. Any lesion that can feasibly exist must be anticipated to be present in some patient at some time. Some lesions, nonetheless, are particularly frequent, such as deficiencies of the floor of the oval foramen, producing an interatrial communication. An intact atrial septum can also produce problems in the setting of absence of the left atrioventricular connection. Persistent patency of the arterial duct is frequent, this being an important part of the circulation when there is pulmonary stenosis or atresia, or aortic coarctation or interruption. It is the obstructive lesions in one or the other of the outflow tracts, nonetheless, which are probably the most important associated lesions. In the setting of a dominant left ventricle, deviation of the muscular outlet septum can produce either subpulmonary or subaortic obstruction, depending on whether the ventriculo-arterial connections are concordant or discordant. A deviated outlet septum can also produce either subpulmonary or subaortic obstruction in the setting of double outlet ventricle. Subarterial obstruction can also be produced by tissue tags, or by anomalous attachment of the tension apparatus of the atrioventricular valves. Other lesions of the pulmonary pathways must be anticipated, such as discontinuous pulmonary arteries, whilst anomalies of venous connection are by no means infrequent, particularly when there is isomerism of the atrial appendages. And the atrial appendages themselves can be juxtaposed. In short, a multitude of associated malformations can be found in patients having

Figure 31-15 This picture, taken from the front, shows the small right ventricle in the setting of double inlet left ventricle, but with a restrictive interventricular communication, producing subaortic obstruction in this instance, since the aorta arises from the small right ventricle. Note that the defect has exclusively muscular borders, opening to the right ventricle between the outlet and apical trabecular components of the chamber.

Figure 31-16 The picture shows the postero-inferior incomplete left ventricle, in left-sided position, from the heart also shown in Figure 31-13. The interventricular communication is perimembranous, being roofed by fibrous continuity between the leaflets of the straddling left atrioventricular valve and the right atrioventricular valve.

either double inlet ventricle or absence of one atrioventricular connection.

Conduction Axis

An understanding of the structure of hearts with univentricular atrioventricular connection, as described above, provides the information needed to determine the location of the atrioventricular conduction axis. This is because the ventricular components of the conduction axis are carried on the crest of the apical muscular ventricular septum, and the atrioventricular node, or in some instances nodes, is formed at the point, or points, of union of the apical septum with the atrioventricular junctions.

When the left ventricle is dominant, the atrioventricular conduction axis is grossly abnormal.^{9,10} The pattern is dictated by the lack of any ventricular septum at the crux. Because of this, the regular atrioventricular node in the atrial septum is unable to make contact with the atrioventricular conduction tissues positioned astride the apical ventricular septum. Instead, an anomalous atrioventricular node is found in the superior quadrant of the right atrioventricular orifice (Fig. 31-17). From this node, the conduction axis penetrates the atrioventricular fibrous plane, the precise course of the non-branching bundle then depending on the position of the incomplete right ventricle. When the right ventricle is right sided, the bundle is able to descend directly onto the septum, and is unrelated to the

pulmonary outflow tract. When the incomplete ventricle is left sided, the bundle extends antero-superiorly around the pulmonary valvar orifice to reach the septum. Irrespective of the position of the right ventricle, the relation of conduction tissue and the interventricular communication is the same when viewed from the right ventricular aspect (Fig. 31-18). The conduction axis branches on the left ventricular aspect of the septum, and is well below the septal crest. Only the right bundle branch extends upwards, piercing the septum to ramify in the apical component of the incomplete right ventricle. The basic disposition of the axis, therefore, is always the same, being dictated by the orientation of the ventricular septum. The septum joins the atrioventricular junction more parietally when there is straddling and over-riding of the right atrioventricular valve. Because of this, the node and penetrating bundle are formed postero-laterally in the right atrioventricular orifice (see Chapter 33). The position of the conduction axis relative to the interventricular communication is the same be there absence of the right or left atrioventricular connection. One important variation is found, however, should there be an apical muscular interventricular communication in addition to the usual defect between the outlet and apical components of the muscular septum. In the presence of two defects, the conduction axis courses within the muscular bar separating the holes (Fig. 31-19). A further variation is found in the setting of tricuspid atresia due to absence of the right atrioventricular connection. Because there is no right atrioventricular valvar orifice, the atrioventricular node is found adjacent to the dimple, with the apex of the triangle of Koch now serving as a guide to the location of the node (Fig. 31-20).

When the right ventricle is dominant, the disposition of the conduction axis is determined in part by the septal orientation, and in part by ventricular topology. Hearts with left-sided incomplete left ventricles have a right-handed pattern of ventricular topology. Then, because the septum extends to the crux, the connecting node is in its anticipated regular position. The atrioventricular bundle penetrates postero-inferiorly, and branches astride the apical muscular

Figure 31-17 This specimen with double inlet left ventricle and discordant ventriculo-arterial connections has been opened in clam-like fashion, and the superior wall reflected upward to show the double inlet through two atrioventricular valves (RAVV, LAVV). The course of the atrioventricular conduction axis has been superimposed using red cross-hatching. The branching bundle is on the crest of the hypoplastic ventricular septum, with the right bundle branch shown in dashes. The atrioventricular node is placed superiorly in the right atrioventricular junction, with the bundle joining these two components (see text for further discussion).

Figure 31-18 The incomplete right ventricle shown in Figure 31-15 has been reoriented to show the view that might be obtained by the surgeon working within this chamber. The head of the patient would be to the left hand. The red oval shows the site of the atrioventricular node in the superior quadrant of the right atrioventricular junction (see Fig. 31-17). The course of the axis within the dominant left ventricle is shown by the large red dotted line. The smaller red dotted lines show the location of the left bundle branch in the dominant ventricle, with the right bundle branch shown by the solid red line. The green area is the part of the septum that can safely be resected if there is need, as there would be in this heart, to enlarge the interventricular communication.

Figure 31-19 The cartoon shows the interior of the incomplete right ventricle as it might be viewed by the surgeon in a patient with tricuspid atresia, and a muscular apical defect in addition to the regular muscular interventricular communication. As is shown, the atrioventricular conduction axis would run in the muscular bar between the holes. (Modified from the original prepared for *Surgical Anatomy of the Heart*, with permission of Gemma Price, Andrew Cook, and Benson Wilcox.)

Figure 31-20 The image shows the right atrium in the heart from a patient with classical tricuspid atresia. The red dots show the site of the atrioventricular node, adjacent to the dimple, where there is absence of the right atrioventricular connection.

septum.¹¹ When the left ventricle is right sided, the ventricular topology is left-handed. This is then the dominant feature in determining the location of the conduction tissue, over and above the fact that the septum reaches to the crux. In the only heart of this type we studied histologically, there was a sling of conduction tissue between anterior and regular nodes. The ventricular conduction tissue descended on a trabeculation within the right ventricle.¹² We anticipate that the same rules will apply when either the right or left atrioventricular connection is absent in association with univentricular connection to a dominant right ventricle.

When there is a solitary and indeterminate ventricle, then because there is no apical trabecular septum, there cannot be a normal conduction system. Most frequently, in our experience,¹³ there has been an anterior node with the bundle descending onto a free-standing muscle bar. The bundle can also descend in the parietal ventricular wall or else drop from a regular node. Slings of conduction tissue have been found in the postero-inferior ventricular wall in patients with right isomerism.¹⁴

Huge Ventricular Septal Defects

Hearts also exist in which most of the ventricular septum is absent, but an apical muscular rim persists, dividing the ventricular mass into right ventricular and left ventricular components (Fig. 31-21). Because of the presence of the apical remnant of the ventricular septum, the ventricular inlets in this setting are committed to recognisably separate

Figure 31-21 This heart is from a patient with a huge interventricular communication. The apical septum, which separates the apical trabecular components of the right and left ventricles, each receiving a separate atrioventricular valve (RAVV, LAVV), continues between the valves as an inlet ridge, which carries the atrioventricular conduction axis from the atrioventricular node at the apex of the triangle of Koch.

apical ventricular components. More importantly, in most cases but not all, it is usual to find a rim of septum extending from the apical septum to the crux. In our experience, this rim has always carried the non-branching bundle from a regularly positioned node. Morphologically, therefore, the hearts are readily distinguished from those with double inlet atrioventricular connection. We categorise them as huge ventricular septal defects, diagnosing the atrioventricular connections according to the union of the atrial chambers with the apical ventricular components.

Morphogenesis

The problems arising from morphogenesis relate as much to terminology of the embryonic heart tube as they do to positive disagreements. When considering the occurrence of double inlet connection, therefore, we should remember that, initially, the orifice of the atrioventricular canal was supported almost exclusively above the inlet part of the primary heart tube, with the presumptive arterial pedicles supported by the outlet component (Fig. 31-22). As described in Chapter 3, the apical component of the developing left ventricle balloons from the inlet component of the ventricular loop, while that of the developing right ventricle balloons from the outlet part. The ballooning of the two apical ventricular components occurs concomitant with development of the apical muscular septum. If the two pouches did not grow separately, but rather there was formation of a general apical component from the primary heart tube, then the end result would be a solitary ventricle of indeterminate morphology (see Fig. 31-22, left hand panel). Whether the atrioventricular junctions are guarded by two valves, or a common atrioventricular valve, depends on the partitioning of the atrioventricular

junction. Should the pouches form in normal fashion, but the atrioventricular junction remain connected only to the inlet part of the ventricular loop, then the end result would be double inlet left ventricle. The hypoplastic trabecular component derived from the outlet part of the loop would form the basis of the incomplete right ventricle (see Fig. 31-22, lower right hand panel). Again, the arrangement of the atrioventricular valves would depend upon the mode of development of the atrioventricular junction. The ventriculo-arterial connections present would depend on the development of the outlet portions. The position of the incomplete right ventricle would probably be determined by the initial looping of the primary tube, but equally it could be influenced by rotation of the entire heart.

Double inlet right ventricle results from transfer of the entire inlet part of the primary heart tube to the apical component derived from the outlet, this process occurring subsequent to formation of the apical component of the left ventricle (see Fig. 31-22, upper right hand panel). This apical component will then form the basis of the postero-inferiorly located incomplete left ventricle. Valvar morphology, and ventriculo-arterial connections, will again depend on the development of the other parts of the heart tube. The position of the incomplete ventricle will depend on the initial direction of ventricular looping. Rightward looping will give a left-sided rudimentary left ventricle, while leftward looping will result in a right-sided left ventricle. The morphogenesis of straddling and overriding valves is discussed in Chapter 33.

Absence of an atrioventricular connection is much harder to explain. Any offered hypothesis must account for the known anatomical facts, namely, that in the setting of absence of the right connection, the left atrium can be connected to a morphologically left, right or indeterminate

Figure 31-22 The cartoon shows the hypothetical steps that could produce the various form of double inlet ventricle.

ventricle. In each of these circumstances, the right atrial anatomy is indistinguishable, as is the left atrial anatomy in the setting of absence of the left connection, irrespective of whether the right atrium is connected to a morphologically right, left or indeterminate ventricle. The most likely explanation, therefore, is that atrioventricular junctions developed as though to produce double inlet connection, but for some reason the right, or left, atrioventricular orifice failed to develop. Indeed, examination of the developing human heart has shown that a stage exists early in its formation which is remarkably similar to absence of the right atrioventricular connection, albeit prior to formation of the atrial septum.¹⁵

EPIDEMIOLOGY

Double inlet ventricle occurred in 1.5% of patients with congenitally malformed hearts seen at the Hospital for Sick Children, Toronto, between 1950 and 1973. The ratio of males to females was 1.25 to 1,¹⁶ although difficulties in diagnosis, particularly in the days before cross sectional echocardiography, cast some doubt on the reliability of this figure. In 378 siblings of patients with double inlet ventricle, the overall incidence of congenital heart disease was 2.8%.¹⁷ Although numbers were small, malformations were more frequent in the siblings of patients with isomerism of the left atrial appendages. When characteristics of infants with double inlet ventricle and their parents were compared with randomly selected controls,¹⁸ paternal consumption of alcohol, smoking, and use of marijuana were associated with increased risk of double inlet ventricle in the offspring, particularly when associated with isomerism. Around 1% of a cohort of more than 1 million infants born in Atlanta between 1968 and 2000 were found to have tricuspid atresia,¹⁹ with advanced maternal age associated with an increased incidence. Tricuspid atresia, along with transposition and common arterial trunk, was also found more frequently in offspring of women with diabetes mellitus.²⁰

PATHOPHYSIOLOGY

Mixing of Blood

The major consequence of the univentricular atrioventricular connection is obligatory mixing of the pulmonary and systemic venous streams in the dominant ventricle, irrespective of its morphology. This mixing will, in general, be complete in most patients in whom an atrioventricular connection is absent, albeit in only a third of those with double inlet ventricle. In the latter setting, of course, it is guaranteed to be complete only if one cardiac valve is imperforate. In those with double inlet left ventricle, preferential streaming does not appear to be affected by obstruction of the subpulmonary outflow, but it is strongly influenced by the position of the incomplete ventricle. Consequently, patients with usual atrial arrangement and a right-sided incomplete right ventricle tend to have favourable streaming in the presence of concordant ventriculo-arterial connections, and unfavourable streaming when the ventriculo-arterial connections are discordant. This is because the systemic venous blood preferentially enters the incomplete right ventricle. In contrast, if the right ventricle is to the left, and connected to the aorta, it is closer to

the left atrioventricular valve and, therefore, preferentially receives pulmonary venous blood.

Atrial Septal Defect

Where there is absence of an atrioventricular connection, the predominant egress of blood from the affected atrium is through an atrial septal defect, although in some in whom there is absence of the left atrioventricular connection, a laevoatrial cardinal vein may contribute. Significant obstruction to the atrial septal defect is manifest in the patient with absent right atrioventricular connection in the form of hepatic enlargement and a reduced cardiac output, while the patient with absent left atrioventricular connection will demonstrate evidence of pulmonary venous congestion and hypoxaemia. Significant obstruction across the atrial septal defect may be important in the patient with double inlet ventricle in one of two settings. The first is when there is stenosis of one of the atrioventricular valves, and the second is where streaming is unfavourable. In the latter situation, an atrial septostomy may reduce the effects of unfavourable streaming and enhance systemic oxygenation.

Pulmonary and Systemic Flows

Clinical presentation is independent of ventricular morphology, but strongly related to the presence of associated lesions. As discussed above, patients with restriction to the pulmonary venous return tend to present in early infancy with pulmonary congestion and hypoxaemia. In patients with absent right atrioventricular connection, restriction of the interatrial communication may result in hepatic congestion. Apart from this, the mode of presentation is almost entirely dependent on the degree of restriction to the pulmonary or systemic circulations. At one extreme are patients with pulmonary atresia, who present with severe cyanosis shortly after birth. If no pulmonary stenosis is present, infants present in the first month or two of life with signs of increased pulmonary flow, often without clinically evident cyanosis. This is exacerbated by the co-existence of interruption of the aortic arch or coarctation, which has been reported in about one-third of autopsied cases where the aorta arises from the incomplete right ventricle, frequently in association with obstruction at a subaortic interventricular communication. It is much rarer if the aorta arises from the dominant ventricle. In the latter situation, it is related to postero-caudal deviation of the outlet septum into the subaortic region. In between the Scylla of severe cyanosis, and the Charybdis of flooded lungs, lies just the right amount of pulmonary stenosis. Patients in this favourable category may present as asymptomatic children, or even as adults with murmurs detected at routine physical examination.

CLINICAL FINDINGS

Although the majority of patients present in the neonatal period or early infancy, the timing and exact clinical presentation will always be dictated by the associated anomalies and their severity. When there is severe obstruction of flow to the lungs, presentation is usually in the neonatal period with a duct-dependent pulmonary circulation. Cyanosis will be present at birth, and will become more severe with

impending closure of the arterial duct. There will be a single second heart sound, a short ejection systolic murmur of pulmonary stenosis at the upper left sternal edge, and sometimes a soft continuous ductal murmur. When there is pulmonary atresia, there will be a single second heart sound, and frequently a continuous murmur from the arterial duct. In contrast, an infant with aortic coarctation will exhibit weak or absent femoral pulses, mild central cyanosis, and symptoms of high pulmonary blood flow, including tachypnoea, enlargement of the liver, and difficulties with feeding. When there is severe aortic coarctation, or aortic interruption, presentation may be with shock during the early neonatal period. Similarly, although the infant with a large interventricular communication will usually be symptom free at birth, the pulmonary vascular resistance will have fallen sufficiently by the beginning of the second month of life for the symptoms and signs of increased pulmonary flow to have become evident. In contrast, the infant with balanced systemic and pulmonary flows because of moderate pulmonary stenosis will be well, with mild central cyanosis and a systolic murmur heard best at the lower left sternal edge. Should the degree of obstruction to pulmonary flow increase, cyanosis will become more obvious, and cyanotic spells might occur.

INVESTIGATIONS

Electrocardiography

In theory, electrocardiography should be very useful in these patients, given the abnormal position of the conduction system and the abnormal size of the ventricles. Correlation might be expected between the direction of the initial QRS vector and the orientation of the ventricular septum, and between the progression of the R wave across the precordium with the relative positions of the dominant and incomplete ventricles.

The standard surface electrocardiogram reveals a leftward superior axis in more than four-fifths of patients in whom the right atrioventricular connection is absent. An electrical axis between 0 and +90 degrees occurs in approximately one-tenth of patients, occurring more frequently, but not exclusively, when the ventriculo-arterial connections are discordant. In the majority of patients in whom the left atrioventricular connection is absent, the frontal QRS axis is between +90 and +180 degrees. The frontal QRS axis can be highly variable in patients with double inlet ventricle. Vectorcardiograms, for example, did not usefully distinguish patients with double inlet ventricle from those with large interventricular communications and comparable ventriculo-arterial connections.²¹

In patients with tricuspid atresia, a pattern of left ventricular dominance is seen in the majority, while right ventricular hypertrophy is associated with unusual anatomical arrangements, including that in which the left atrium connects to a dominant right ventricle. In those in whom the left atrioventricular connection is absent, the typical pattern of the ventricular forces tends to indicate right ventricular dominance. In patients with double inlet left ventricle, a pattern of left ventricular dominance occurs more commonly in those with right-sided incomplete right ventricles, while a pattern of right ventricular dominance is found in most having double inlet right ventricle. It is possible to make sense of the electrocardiogram, therefore, when the diagnosis is known. Making the

diagnosis from the electrocardiogram, in contrast, is much more difficult.

Chest Radiography

There is no particular configuration of the cardiac outline that typifies the patient with a univentricular atrioventricular connection. Abnormalities present on plain chest radiography are the consequence of malposition of the heart, the relatively high incidence of isomerism, and the high incidence of discordant ventriculo-arterial connections or abnormally related great arteries. Left-sided incomplete right ventricles occasionally protrude from the left border of the heart in a characteristic fashion in those with double inlet left ventricle. A prominent right heart border, reflecting right atrial distension, may suggest a restrictive interatrial communication in a patient with tricuspid atresia.

There is a close correlation between the size of the heart and the volume of flow to the lungs. With diminished pulmonary flow, the size of the heart remains normal, although in the absence of pulmonary stenosis, when pulmonary flow is increased, cardiomegaly is the rule. If the pulmonary vascularity is increased, and the heart is greatly enlarged, and yet the child is markedly cyanotic, the inference can be drawn for markedly unfavourable streaming of blood within the heart, or possibly obstruction to pulmonary venous return.

Transthoracic Echocardiography

M-mode Tracings

Considerable attention was directed to the inferential echocardiographic diagnosis of a univentricular atrioventricular connection using M-mode techniques. These studies remain of historical interest, but since the advent of cross sectional techniques are no longer useful in the anatomical delineation of these hearts.

Cross Sectional Echocardiography

As in any congenital cardiac lesion, accurate echocardiographic diagnosis is facilitated by use of the segmental approach. Given the complexity of these hearts, a systematic approach is of particular importance. Having determined the atrial arrangement, the examination proceeds to the delineation of the atrioventricular connections. The key to the diagnosis of double inlet ventricle lies in the demonstration of two atrioventricular valves, one of which may be imperforate, or a common valve, opening into one ventricle. In hearts with absent atrioventricular connection, the prominent atrioventricular groove, which may contain fibro-fatty tissue, will be seen interposing between the floor of the atrium and the ventricular mass. These appearances are best demonstrated from the subcostal (Figs. 31-23 and 31-24) or apical windows (Fig. 31-25), with the transducer oriented so as to demonstrate both atriums and both atrioventricular valves (Fig. 31-26). This is the cut that would normally produce a four-chamber section. In patients with double inlet ventricle, it is sometimes difficult to see both junctions in the same plane, particularly from the subcostal position, but slight rocking of the transducer from side to side so as to bring first one valve and then the other into view, while recording continuously, will normally produce the necessary information. In patients with double inlet ventricle, the relations between the atrioventricular junction and the ventricular septum should be assessed for overriding. If this exists, biventricular connections must

Figure 31-23 These images obtained from a subcostal window demonstrate double inlet left ventricle via two atrioventricular valves. Panel A demonstrates the size of the atrioventricular valves (arrows), while slight anterior angulation (B) demonstrates the aorta (Ao) which arises from the dominant ventricle.

Figure 31-24 In this image, obtained from a subcostal window, in a patient with isomerism of the right atrial appendages, it can be seen that both atrial chambers connect to the dominant ventricle through a common atrioventricular valve.

Figure 31-25 The image is obtained from an apical window in a patient with tricuspid atresia. The fibro-fatty tissue within the atrioventricular groove (arrow) is seen separating the right atrium (RA) from the ventricular mass. This is the consequence of absence of the right atrioventricular connection. LA, left atrium; LV, left ventricle.

be distinguished from the univentricular connection by applying the 50% rule. Precordial short-axis cuts, on occasion, can demonstrate well the double inlet connection.

Should an imperforate valve exist in the setting of double inlet ventricle, it is seen as a thin mobile echo between one or the other atrium and the dominant ventricle, sometimes with tension apparatus inserting into it. If this is suspected, it is important to scan from front to back of the heart to ensure that it is not the valvar annulus that is being misinterpreted as an imperforate valve. A common valve appears quite different from a single valve to the experienced observer, resembling closely the common atrioventricular orifice of atrioventricular septal defects. The easiest way to recognise a common atrioventricular junction is to identify the so-called ostium primum defect, which has always been present in cases described so far. In patients in whom one of the atrioventricular connections is absent, care should be taken to document abnormalities of the solitary atrioventricular valve, which are common.²²

In hearts with one big and one small ventricle, short- and long-axis scans from subcostal or precordial windows demonstrate the malaligned and hypoplastic muscular ventricular septum. Such cuts also demonstrate well the relation of the incomplete and dominant ventricles. These spatial relationships as seen in the long- and short-axis planes are most useful in determining the morphology of the ventricles. In hearts in which the left ventricle is dominant, the incomplete right ventricle is always carried on its antero-superior shoulder. In contrast, in hearts with dominant right ventricles, the incomplete left ventricle occupies a postero-inferior position. If a second ventricle is not identified, the ventricular morphology is presumed to be indeterminate. Once the existence and morphology of any incomplete ventricle has been determined, the ventriculo-arterial connections can be established by tracing the arterial roots in subcostal or precordial long-axis cuts until they can be identified as either aorta or pulmonary trunk. Similar cuts will also demonstrate the nature of any subvalvar obstruction.

Having established the basic anatomy, using the sequential approach, other features must be considered. Abnormalities of systemic (Fig. 31-27) and pulmonary venous return (Fig. 31-28) can usually be readily identified from

Figure 31-26 These images are obtained from an apical window in a patient with double inlet left ventricle via two atrioventricular valves (A). Slight anterior angulation of the transducer (B) demonstrates an unrestrictive communication (*arrow*) between the dominant left ventricle and the incomplete right ventricle (RV), which gives rise to the aorta.

Figure 31-27 These images, obtained from a subcostal window in a patient with isomerism of the left atrial appendages, show azygos (Az.) continuation of the abdominal venous return to the superior caval vein (SCV). The colour flow seen in the right panel shows the flow from the superior caval vein into the heart.

Figure 31-28 These images are obtained from a subcostal window in a patient with isomerism of the right atrial appendages and double inlet ventricle. The pulmonary veins drain to a confluence (C). There is restrictive egress from the confluence (A), which results in distension of the pulmonary veins (*arrows* in B).

subcostal, parasternal, and suprasternal views. Identification of bilateral superior caval veins will assume greater importance in planning cavopulmonary shunts. Considerable attention should be directed to the assessment of the interventricular communication (Fig. 31-29). The muscular, perimembranous, doubly committed or multiple nature of such defects can readily be identified. Measurements of

the interventricular communication should be performed in two planes, usually taking the maximal diameters in both the short- and long-axis projections. These measurements can be used to calculate the area of the interventricular communication using the formula for a regular ellipse, which can be indexed either to body surface area²³ or to the cross sectional area of the aorta. When available,

Figure 31-29 This image is again obtained from a subcostal window in a patient with double inlet ventricle. The interventricular communication (arrow) and the incomplete and small right ventricle (RV) can be seen. The aorta (Ao) arises from the dominant left ventricle (LV).

three-dimensional echocardiography may be useful. It has been shown to provide accurate measurements of the size of the interventricular communication in cardiac specimens, and in a small group of patients.²⁴ Careful attention must be paid to the aortic arch to exclude either interruption or coarctation, particularly in those in whom the aorta arises from the incomplete ventricle (Figs. 31-30 and 31-31).

Because abnormalities of the atrioventricular valves are frequent, particular attention should be paid to their size and tension apparatus, using multiple cuts as necessary. Colour mapping and Doppler interrogation is of value in detecting valvar regurgitation, although it may be misleading in the assessment of stenosis in patients with double inlet ventricle in the presence of an interatrial communication. The examination is modified accordingly when the heart is in the middle or to the right of the chest, but the basic principles of diagnosis remain the same.

Fetal Echocardiography

Fetal ultrasonic scanning is now a routine part of antenatal care in many countries, and consequently increasing numbers of cardiac anomalies are being detected prior to birth. Data from the 12 registries included in the Eurocat study revealed that, between 1990 and 1994, half of those with double inlet ventricle, and more than two-fifths of those with tricuspid atresia, were diagnosed in this fashion.²⁵ Nuchal thickening is an established marker for the presence of congenital cardiac disease in fetal life. Using this feature, one study²⁶ found one-sixth of patients with congenitally malformed hearts and normal chromosomes to have tricuspid atresia. In a series of patients diagnosed prenatally with tricuspid atresia, almost three-tenths were either terminated or died prior to birth. Of those surviving to active management, the probability of survival was 91% at 1 month, 87% at 6 months, and 83% at 1 year. Multi-variate analysis revealed that the presence of a chromosomal anomaly or syndrome, and the requirement for

Figure 31-30 These images are obtained from high parasternal and suprasternal windows in a patient with double inlet left ventricle and discordant ventriculo-arterial connections. The size of the aortic valve is similar to that of the pulmonary valve (Pulm in A), and the aortic arch is unobstructed (B). Parasternal images had revealed a large interventricular communication. Ao, aorta.

Figure 31-31 These images are obtained from a suprasternal window in a patient with double inlet left ventricle and discordant ventriculo-arterial connections. The aortic valve is considerably smaller than the pulmonary valve. The distal portion of the aortic arch is hypoplastic and obstructed (arrow). Parasternal imaging had demonstrated a restrictive interventricular communication, resulting in subaortic obstruction. Ao, aorta; PT, pulmonary trunk.

extracorporeal membrane oxygenation, were independent risk factors for death.²⁷ An important potential benefit of antenatal diagnosis overall is that it permits transfer of fetuses with potentially duct-dependent systemic or pulmonary circulations for delivery and treatment in specialist centres, resulting in improved survival. Such benefits have yet to be proven, nonetheless, for fetuses known to have either double inlet ventricle or tricuspid atresia. In a study of patients with isomeric atrial appendages, with over half diagnosed antenatally, diagnosis during fetal life did not improve survival.²⁸

Nuclear Imaging

Nuclear imaging is of little value in the diagnosis of patients with univentricular atrioventricular connection.

Magnetic Resonance Imaging

The recent widespread use of magnetic resonance imaging has provided exciting new insights into the anatomy and pathophysiology of those having univentricular atrioventricular connections.²⁹ Magnetic resonance imaging can provide a complete sequential diagnosis in most patients (Fig. 31-32). It is of particular value in those in whom echocardiographic images are suboptimal. Its ability to demonstrate the distal portions of the pulmonary arteries, and the function of the morphologically abnormal ventricles, may be of particular interest. In some centres, magnetic resonance imaging has established a central role in planning for intermediate palliation,³⁰ making cardiac catheterisation unnecessary. It is unlikely, however, that the technique will, in the near future, entirely replace cardiac catheterisation in the assessment of the patient prior to definitive palliation.

Cardiac Catheterisation

It has been suggested that, in many patients, advances in non-invasive investigative techniques may make cardiac catheterisation unnecessary prior to definitive palliation.^{31,32} In our centre, nonetheless, at least for now, we

continue to recommend cardiac catheterisation in all such patients. This is principally because of the necessity to measure the flow of blood to the lungs, along with pulmonary resistance, but also because of the difficulty in recognising mild degrees of subaortic obstruction, which occurs most commonly in patients in whom the left ventricle is dominant, and the aorta arises from the incomplete right ventricle.³³

Cardiac catheterisation is almost always performed using a femoral approach, although, in patients after a bidirectional cavopulmonary anastomosis, cannulation of the internal jugular vein also is necessary if the cavopulmonary anastomosis is the only source of flow to the lungs. The dominant ventricle is usually entered with ease, although difficulties may be encountered entering the artery supported by it. Use of a flow-directed balloon catheter may be helpful. If not, retrograde arterial catheterisation almost always succeeds when the catheter is passed through the aortic valve and looped in the dominant ventricle. Entry into the dominant left ventricle from a retrograde arterial approach, nonetheless, must be performed with extreme caution in the patient with double inlet left ventricle and discordant ventriculoarterial connections, as it may result in subaortic obstruction or damage to the aortic valve. Careful withdrawals across the interventricular communication should be recorded to document any obstruction at that site.

The pulmonary arteries must always be entered in order to assess pulmonary vascular anatomy and physiology. When it is not possible to enter the pulmonary arteries, it has been suggested that measurements of a pulmonary venous wedge pressure may provide an estimate of pressure in the pulmonary arteries. Such measurements provided a relatively accurate estimate of the pressure in the pulmonary arteries when this was less than 18 mm Hg.³⁴ In patients in whom the aorta arises from the incomplete right ventricle, an intravenous infusion of isoprenaline can be used to provoke a gradient across the interventricular communication while simultaneously measuring left ventricular and ascending aortic pressures. Careful withdrawal around the aortic arch will aid in the exclusion of obstruction within the arch (Fig. 31-33).

Angiocardiography

The investigator who can produce high-quality angiocardiograms in patients with a functionally single ventricle will have no difficulty in any other field of angiocardiography. Although a detailed angiographic approach to establishing the diagnosis in patients with a univentricular atrioventricular connection has been described, advances in non-invasive imaging have now rendered this approach obsolete.

If performed, injections into the dominant ventricle show the interventricular communication (Fig. 31-34), demonstrate the relationships between the two ventricles, serve to exclude incompetence of the atrioventricular valves (Fig. 31-35), and function to opacify the systemic and pulmonary outflow tracts. Opacification of the volume-overloaded dominant ventricle usually requires injection of 1.8 to 2 mL/kg of contrast medium. Biplane cineangiography is recommended, with one intensifier providing a lateral projection. Information obtained from the transthoracic echocardiogram may help in planning the optimal position of the second intensifier. In patients

Figure 31-32 This magnetic resonance image is profiled in four-chamber projection and obtained in a patient with tricuspid atresia. The fibrofatty tissue within the atrioventricular groove (arrow) is shown separating the right atrium from the ventricular mass. Ant., anterior; L, left; post., posterior; R, right.

Figure 31-33 Illustrative haemodynamic and oximetric data from a patient with tricuspid atresia and concordant ventriculo-arterial connections (A), and double inlet left ventricle with discordant ventriculo-arterial connections (B). Panel A shows the situation with restricted pulmonary flow, so that the pulmonary arterial pressure is lower than systemic. The saturation of oxygen in the aorta is 72%, because of the low pulmonary flow. The atrial septal defect is restrictive, resulting in a drop in pressure across the atrial septum. In panel B, there is a drop in pressure between the left ventricle and the aorta, which reflects restriction at the level of the interventricular communication and a further drop in pressure across the aortic arch, reflecting the presence of aortic coarctation. The saturation of oxygen in the aorta is slightly higher than that in the pulmonary arteries because of a minor degree of streaming.

Figure 31-34 These ventriculograms were performed in the dominant left ventricle in a patient with a solitary interventricular (LV) communication (A), and one with multiple interventricular communications (arrows in B). RV, right ventricle.

with a dominant right ventricle, or a dominant left ventricle with a left-sided incomplete right ventricle, an anteroposterior projection is chosen. These projections also serve to identify the solitary and indeterminate ventricle when the apical trabeculations are coarse and it is not possible to identify a second ventricle. In patients with a dominant left ventricle and a right-sided right ventricle, a long-axial projection is usually best in profiling the ventricular septum. This demonstrates well the ventriculo-arterial connections, and also reveals the presence of a common valve. Injections into the small ventricle can provide further imaging of the interventricular communication, and demonstrate obstruction within the cavity of the small ventricle itself.

Pulmonary angiography should be performed in all patients prior to definitive palliation. The size of the pulmonary arteries can be measured and indexed to either the surface area of the body or to the aorta. Distortion of the pulmonary arteries, or pulmonary arterial stenoses, can be demonstrated, and the pattern of pulmonary venous return delineated. In patients after staged palliation with

either systemic-to-pulmonary arterial or cavopulmonary shunts, further angiograms are required to verify patency of the shunt (Fig. 31-36), while in others, caval venous injections (Fig. 31-37), and/or angiography of the aortic arch (Fig. 31-38), will be necessary.

Biopsy of the Lung

Given the importance of the pulmonary vasculature in determining outcomes after definitive palliation, biopsies of the lung were formerly frequent in assessing potentially high-risk patients. Although biopsies are now rarely performed, a recent study analysed biopsies from patients who were considered to be good candidates for definitive palliation, to determine whether pulmonary histology could predict failure. Specimens were abnormal in almost half of patients with low pulmonary arterial pressure. While there was no relationship between preoperative pulmonary arterial pressure and outcome, extension of muscle into peripheral arteries was always present in cases of failure of

Figure 31-35 This ventriculogram was performed in the dominant ventricle of a patient with double inlet left ventricle via two atrioventricular valves. The atrioventricular valves can be seen *en face* with the reds arrowheads showing the orifice of the right atrioventricular valve, and the yellow arrowheads the orifice of the left valve. Ao, aorta.

Figure 31-36 The angiogram was performed in the superior caval vein (SCV) in a patient in whom a bidirectional cavopulmonary shunt has been completed. The shunt is widely patent, and the right and left pulmonary arteries can be easily seen. L, left; R, right.

the Fontan procedure. It was concluded that histomorphometric examination of pulmonary biopsies may still be a useful adjunct to the usual criterions for selection of therapeutic options in some patients.³⁵

MANAGEMENT

Medical Management

Neonates with cyanosis and duct-dependent pulmonary flow usually improve rapidly once ductal patency is re-established by intravenous infusion of prostaglandin E.

Figure 31-37 In this patient with tricuspid atresia and a left superior caval vein (LSCV) connected to the coronary sinus, a catheter has been passed from the femoral vein through the coronary sinus to the left superior caval vein, and an angiogram has been performed.

Figure 31-38 An aortogram in this patient with double inlet left ventricle and diminutive pulmonary arteries revealed a major aortopulmonary collateral artery (MAPCA), which perfused the right lung.

A poor response to prostaglandin, particularly in the setting of right isomerism, may indicate obstructed pulmonary venous return. In these patients, supportive care, with mechanical ventilation and correction of acidosis, may provide temporary stability while awaiting urgent surgery. Patients with obstructed systemic circulation and duct-dependent systemic blood flow may be in critical condition, with poor peripheral pulses, acidosis, and oliguria. Again, infusion of prostaglandin E, combined with manoeuvres to augment pulmonary vascular resistance, may be life saving.

Once ductal patency is established in those with duct-dependent circulations, medical management is directed to optimizing the delicate balance between systemic and pulmonary flows. This is achieved by gentle reduction of systemic afterload, combined with manoeuvres to augment pulmonary vascular resistance, including positive pressure ventilation with a fraction of inspired oxygen between 0.21 and 0.25.

Surgical Management

Initial Palliative Surgery

Initial surgical palliation is performed in order to allow survival in the short term, and to set the scene for definitive palliation at low risk. This is achieved, first, by ensuring that there is adequate, although not excessive, flow at low pressure through a low-resistance, non-distorted pulmonary vascular bed. The second prerequisite is to optimise systemic outflow in those with subaortic or aortic arch obstruction. The third is to ensure that systemic and pulmonary venous return is unobstructed. In a large cohort of patients with functionally univentricular hearts treated between 1988 and 2000, just under two-fifths were initially palliated using only a systemic-to-pulmonary arterial shunt, one-fifth by banding the pulmonary trunk, one-sixth by construction of a bidirectional cavopulmonary shunt, another fifth by conversion to the Fontan circulation, and the remaining one-twentieth by a Norwood operation. Almost one-quarter of the patients died before definitive palliation could be achieved by means of a Fontan operation.³⁶ In another cohort with tricuspid atresia and concordant ventriculo-arterial connections, presenting prior to 2004, antegrade flow in the pulmonary arteries was absent in one-fifth, restricted in half, and unrestricted in three-tenths. Initial palliation included a systemic-to-pulmonary arterial shunt in one-third, banding of the pulmonary trunk in one-tenth, and construction of a cavopulmonary anastomosis in one-quarter. By the age of 2 years, nine-tenths had undergone a cavopulmonary connection, 6% were dead, and 4% remained alive without a cavopulmonary connection. Risk factors for death without a cavopulmonary anastomosis included the presence of mitral regurgitation and the use of systemic-to-pulmonary arterial shunts which did not originate from the brachiocephalic artery. Of those who underwent a cavopulmonary anastomosis, three-quarters had undergone a Fontan operation within 3 years. Overall, after 5 years, 86% of the patients were still alive.³⁷

Patients with Excessive Pulmonary Flow

Banding of the pulmonary trunk is performed to reduce the volume load to the dominant ventricle, to reduce the flow of blood to the lungs and pulmonary arterial pressure, and to prevent the development of pulmonary vascular disease. The role of banding has been controversial in patients in whom the left ventricle is dominant because of a statistical association between this procedure and the development of acquired subaortic obstruction. It remains unclear, however, whether this relationship is a causal one, or just reflects the evolution over time in the size of the muscular interventricular communication.

Banding of the pulmonary trunk may be performed through a left thoracotomy or through a median sternotomy, making limited dissections between the aorta and

pulmonary trunk so as to reduce the risk of distal migration of the band producing stenosis of the pulmonary arterial branches. The size of the band can be predicted according to published formulas, although fine-tuning of the size is usually performed according to systemic and pulmonary arterial pressures and systemic arterial saturations of oxygen. The difficulties in the intra-operative assessment of the adequacy of the band have resulted in the development of a number of novel techniques that permit percutaneous adjustment in the post-operative period.^{38,39} These newer approaches may well reduce mortality and adverse events early after surgery.³⁸

A recent study⁴⁰ has examined outcomes for patients with functionally univentricular circulations undergoing banding of the pulmonary trunk as a primary surgical procedure. In almost half, aortic coarctation or interruption had been repaired at the same procedure, while in almost one-quarter a subsequent procedure was required to relieve subaortic obstruction. Death occurred during the procedure in one-twentieth of the cohort, with additional late deaths bringing the rate of mortality to almost 25%. Overall survival was 84% at 1 year, and 76% at 5 and 15 years. Citing the aforementioned difficulties with banding, nonetheless, it has been suggested⁴¹ that division of the pulmonary trunk and placement of a systemic-to-pulmonary arterial shunt provide an alternative surgical option for patients with excessive flow to the lungs. Using this strategy, the group encountered no operative deaths, and only 1 of their 22 patients died at a later stage. All the patients subsequently underwent a bidirectional cavopulmonary shunt, and almost one-quarter have now been converted to the Fontan circulation, with no additional mortality.

Patients with Inadequate Pulmonary Flow

The modified Blalock-Taussig shunt, in which a graft is interposed between the subclavian or brachiocephalic and the pulmonary arteries, is the procedure of choice. Alternative anastomoses, such as those pioneered by Potts and Waterston, are no longer performed because of their tendency to produce pulmonary arterial distortion and excessive flow to the lungs. Although traditionally the interposition graft has been placed through a thoracotomy, recently some groups have advocated use of a median sternotomy. Potential advantages of this approach are, first, that the shunt can be placed more centrally, facilitating access during further procedures through the midline, and second, that entry to the pleural space is avoided. It has been suggested that shunting into the pulmonary trunk may provide more uniform growth of the pulmonary arteries, compared to when the shunt is inserted directly into them.⁴² In some patients with so-called pulmonary coarctation, it has been suggested that concomitant surgical angioplasty of the pulmonary artery involved by the coarctation lesion may enhance growth of the pulmonary artery on the other side.

The syndrome of a reduced systemic output may complicate the post-operative course of patients after construction of a systemic-to-pulmonary arterial shunt. While most patients will respond to optimisation of ventilation, or to infusions of inotropes or vasodilators at low rates, it has been controversial as to whether patients who do not respond to these therapies should be considered for extracorporeal membrane oxygenation. A review of such

patients supported in this fashion between 1996 and 2005 showed that almost half survived to be discharged from hospital.⁴³ The strongest predictor of outcome was the indication for support, with four-fifths of patients cannulated for hypoxaemia, but only three-tenths of those cannulated for hypotension, surviving to discharge. Those requiring support because of obstruction to flow through the shunt showed the greatest survival, at 83%. Thus, the presence of a systemic-to-pulmonary arterial shunt in the setting of a functionally univentricular circulation should not be considered a contra-indication to extracorporeal membrane oxygenation.

In some patients with obstruction to pulmonary flow, the intrapericardial pulmonary arteries may be diminutive, with most flow to the lungs derived through major systemic-to-pulmonary collateral arteries. In these circumstances, unifocalisation of the pulmonary vasculature can facilitate construction of a cavopulmonary circulation, albeit with nearly half of such patients suffering either early or late mortality.⁴⁴ Of those surviving, nonetheless, a bidirectional cavopulmonary shunt was constructed in all but one, and half of these were converted to the Fontan circulation.

Subaortic Obstruction

In patients with a dominant left ventricle, the development of subaortic obstruction is a major indicator of poor prognosis. In some, subaortic obstruction is overt at birth, when it is often associated with obstruction in the aortic arch and duct-dependent systemic circulation. In others, progressive restriction may develop during postnatal life. While some of these children will have undergone banding of the pulmonary trunk in early infancy, as we have already discussed, a causal relationship between this procedure and the development of subaortic obstruction remains unproven. Progressive subaortic obstruction has certainly been described in patients who have not undergone banding. Indeed, it has been suggested that banding, by keeping the patient alive, allows the interventricular communication to manifest its natural tendency towards a reduction in size.

A number of surgical approaches to this problem have been described, suggesting that none is ideal. Direct relief has been achieved by enlargement of the interventricular communication, combined with enlargement of the cavity of the incomplete right ventricle. This procedure can be performed through the aortic valve or directly through the rudimentary ventricle. In one large series employing this approach, almost half of the patients were younger than 1 year of age.⁴⁵ Previous banding of the pulmonary trunk had been undertaken in over four-fifths of the cohort, and half of these required repair of aortic coarctation. A patch to enlarge the incomplete right ventricle was inserted in all but one. Of the group, one-fifth died in the early post-operative period, but complete heart block requiring insertion of a pacemaker occurred in only two patients (8%). The overall survival at 1 and 3 years was 73%, and at 5 and 10 years was 68% and 60%, respectively.

An alternative approach used to alleviate subaortic obstruction in the neonate is to perform the arterial switch operation, leaving the restrictive interventricular communication to limit the flow of blood to the lungs. Because of differences in sizes of the arterial outflow tracts, the arterial switch is technically difficult in this setting. Furthermore, even minor degrees of pulmonary arterial distortion

secondary to the arterial switch operation may assume greater significance in the patient in whom the eventual treatment requires conversion to the Fontan circulation. We have treated 12 neonates with univentricular atrioventricular connection in this fashion, undertaking concomitant repair of the aortic arch in all but one. Of the group, one-third died either early or later. In the survivors, however, we observed neither recurrence of subaortic obstruction nor aortic valvar incompetence, albeit that we needed to create a modified Blalock–Taussig shunt in two-thirds because of increasing restriction at the level of the interventricular communication. All but one of survivors in the medium term, nonetheless, have now progressed to more definitive palliation by means of cavopulmonary shunting procedures.

It is the creation of an anastomosis between the proximal pulmonary trunk and the ascending aorta, the so-called Damus-Stansel-Kaye procedure, which has been used most frequently as a means of alleviating subaortic obstruction in these patients. Flow of blood to the lungs is ensured by placing an interposition graft between the systemic and pulmonary arteries. In the older infant, it is possible to achieve a cavopulmonary connection,⁴⁶ achieving operative results comparable to those undergoing the Damus-Kaye-Stansel procedure beyond the neonatal period, or those having subaortic resection. Overall mortality, nonetheless, remains high irrespective of the chosen therapeutic option.

Anomalies of Pulmonary Venous Return

Anomalies of pulmonary venous return significantly complicate the care of patients with functionally univentricular circulations at all stages of their care, whether during primary palliation, creation of the bidirectional Glenn shunt, or conversion to the Fontan circulation. These anomalies are most frequent in patients with isomeric atrial appendages.⁴⁷ Obstruction to flow is common in those with totally anomalous pulmonary venous connections, with this feature present in almost one-third of the patients in one large series.⁴⁸ In almost half, repair of the anomalous pulmonary venous return was performed as part of the initial palliative procedure. Although survival was improved in patients undergoing surgery after 1997, only half of the cohort survived to reach the age of 5 years.

Atrial Septectomy

Atrial septectomy may be necessary to improve mixing, or for palliation in patients with associated stenosis of the left atrioventricular valve.

Intermediate Palliation Using a Bidirectional

Cavopulmonary Shunt

In recent years, the classic Glenn shunt, which sacrifices the continuity between the right and left pulmonary arteries, has been replaced by the bidirectional cavopulmonary shunt, in which an end-to-side anastomosis is constructed between the superior caval vein and the undivided right pulmonary artery. The bidirectional shunt has now become widely used as a palliative procedure for all patients with univentricular atrioventricular connections. It is well established that the procedure can be performed with low operative risk, and it has been suggested that use of this shunt may reduce the risk of subsequent conversion to the Fontan circulation.⁴⁹ Its physiological advantage as a palliative procedure is that the volume load on the dominant ventricle is reduced, and often regurgitation of the atrioventricular

valves is alleviated. The operation is usually performed through a median sternotomy, using cardiopulmonary bypass, although it can be performed without cardiopulmonary bypass.⁵⁰ In some centres, a physiologically similar operation, the so-called hemi-Fontan procedure, is performed, which more completely prepares the patient for subsequent conversion to the Fontan circulation.^{51,52}

It remains controversial whether accessory sources of flow of blood to the lungs should be left in place when constructing a bidirectional cavopulmonary shunt. The systemic arterial saturations of oxygen may be higher in patients in whom there is an alternative source of pulmonary flow. It has also been suggested that such an additional source of pulmonary flow may enhance growth of the pulmonary arteries, which is commonly impaired after a bidirectional cavopulmonary shunt.⁵³ Others have shown, nonetheless, that such an accessory source of pulmonary flow fails to confer additional benefits in terms of outcome, either after the bidirectional cavopulmonary shunt itself or after subsequent conversion to the Fontan circulation.⁵⁴ Although, traditionally, the tendency has been to avoid use of this shunt in young infants, recent data has shown an overall mortality of only 4.8% in patients who underwent this procedure before the age of 6 months.⁵⁵ In this series, however, creation of the shunt in the neonatal period proved to be a risk factor for death, prompting the suggestion that the procedure be deferred until after the age of 2 months. Another large series of over 300 patients was collected with early mortality of less than 1%, albeit with 22 later deaths in patients who had not undergone conversion to the Fontan circulation. At the time of follow-up, two-thirds of the cohort had been converted to the Fontan circulation, with mortality of less than 2%. Overall survival at 10 years was 89.8%. Elevated pulmonary arterial pressures, and the presence of isomerism, emerged as independent risk factors for death, takedown, or unsuitability for definitive palliation.⁵⁶ In another large series, freedom from death or transplantation was 96% at 1 year, and 89% at 5 years. In this series, atrioventricular valvar regurgitation proved to be an independent risk factor for death or transplantation.⁵⁷

Definitive Palliation

The ultimate aim of initial and intermediate palliation is to prepare the patient for definitive palliation by conversion to the Fontan circulation. The operation and our understanding of its physiology have developed since the original description of Fontan and Baudet.⁵⁸ The most notable of these developments have been by de Leval and coworkers,⁵⁹ which resulted in the development of the total cavopulmonary shunt, the introduction of fenestration, popularised by the Boston group,⁶⁰ and more recently, the introduction of the extracardiac conduit.⁶¹ The considerations and outcomes related to this procedure are detailed in Chapter 32, and so will not be considered here.

An alternative approach to definitive palliation is to septate the dominant ventricle, which will maintain pulsatile flow in the pulmonary circulation. Ventricular septation for double inlet ventricle was first accomplished in the mid 1950s, with results from reasonably large series published in the 1970s and early 1980s. The major problems with early attempts were the need for ventriculotomy,

the development of obstruction to ventricular outflow due to billowing of the non-contractile patch, and a high incidence of surgically induced heart block. The incidence of these problems was subsequently reduced by the development of transatrial approaches and staging. Imai and co-workers⁶² employed a transatrial approach to septation in a series of 19 patients, many of whom had contraindications to the Fontan approach. Of the patients, one died within 30 days of surgery, while three developed permanent and complete heart block at the time of operation. There were three further deaths within 100 days of surgery. Neither pre-operative mean pulmonary arterial pressure, nor pulmonary vascular resistance, emerged as risk factors, but significant predictors of death were the presence of a high pressure gradient between the dominant ventricle and pulmonary arteries, a high peak systolic pressure, an elevated left ventricular end-diastolic pressure, and a higher body surface area. Based on their experience, Imai and colleagues suggested that septation should only be considered in patients in whom the combined volumes of the right and left ventricles at end-diastole exceeded approximately two and one-half times the expected normal left ventricular end-diastolic volume.⁶³ In a subsequent analysis, the same group observed that ventricular hypertrophy was also a risk factor. Despite the intuitive appeal of achieving a biventricular circulation subsequent to septation, most centres nowadays still recommend the Fontan operation as the definitive palliative procedure in patients with a functionally univentricular circulation.

This useful review summarises the contribution of magnetic resonance imaging to the care of patients with a univentricular atrioventricular connection at all stages of their palliation.

The necessity for routine cardiac catheterisation before definitive palliation of the patient with a univentricular atrioventricular connection is a topic of current debate. These three important articles summarise some of the key issues in the discussion.
- Karamlou T, Ashnurn DA, Caldarone CA, et al, Members of the Congenital Heart Surgeons Society: Matching procedure to morphology improves outcomes in neonates with tricuspid atresia. *J Thorac Cardiovasc Surg* 2005;130:1503–1510.

This important study, on behalf of the Congenital Heart Surgeons society examined outcomes for 150 babies with tricuspid atresia. Antegrade pulmonary blood was absent in 19%, restricted in 54%, and unrestricted in 28%. Overall survival at 5 years was 86%. Initial palliation included systemic-to-pulmonary arterial shunt in 64%, banding of the pulmonary trunk in 11%, and cavopulmonary anastomosis in 24%. Risk factors for death without cavopulmonary anastomosis included the presence of mitral regurgitation and palliation with systemic-to-pulmonary arterial shunts which did not originate from the brachiocephalic artery. Factors associated with decreased transition rate to cavopulmonary connection included variables related to the patient (younger age at admission and the presence of noncardiac anomalies) and variables related to procedures (use of a larger systemic-to-pulmonary arterial shunt diameter). Of patients undergoing cavopulmonary anastomosis, 75% had undergone a Fontan operation within 3 years. The authors concluded that outcomes can be improved by placing smaller shunts from the brachiocephalic artery, especially in patients with regurgitation of the left atrioventricular valve.

The Principles of Management, and Outcomes for, Patients with Functionally Univentricular Hearts

DAMIAN HUTTER and ANDREW N. REDINGTON

In 1699, Chemineau¹ described a human fetus having an allegedly univentricular heart. Since then, the patients characterised as possessing functionally univentricular hearts have held a unique position among all congenital cardiac malformations, not only because of the challenges of describing their diverse morphology, but also because of the continuing difficulties associated with their staged palliative repair, and the uncertainties of their outcomes in the long term. The evolution of thought concerning classification has been described at length in the previous chapter, along with discussions as to the nature of rudimentary, dominant, or incomplete ventricles,^{2–4} and we will not reiterate the arguments here. Suffice it to say that recognition that patients with either biventricular or univentricular atrioventricular connections can exhibit the functionally univentricular arrangement, in which the driving force to both the systemic and pulmonary circulations is provided by but one ventricle, albeit that in most situations a second ventricular chamber is usually to be found within the ventricle mass.⁵

A thorough understanding of the anatomical substrate is necessary fully to understand the resulting physiology, and therapeutic options, in the individual patient. Specific therapeutic algorithms, particularly in terms of decision-making early in life, are also discussed in detail in the preceding chapter (Chapter 31), and those concerned with hypoplasia of either the right or left ventricles (Chapters 29 and 30), these being the major lesions producing the functionally univentricular arrangement. In this chapter, we will endeavor to provide a more generic approach to the understanding of the complexities of the physiology of the circulations produced by the functionally univentricular arrangement, and discuss the late outcomes of repair. No matter what the anatomic diagnosis, the restoration of a normal preload, and optimisation of afterload, to the dominant ventricle represents an overarching physiologic principle, albeit not always achieved, which underscores the current tripartite approach to management. The three stages are early neonatal palliation, followed by construction of a bidirectional cavopulmonary anastomosis, and completed with the creation of the Fontan circulation.

NATURAL HISTORY OF PATIENTS WITH FUNCTIONALLY UNIVENTRICULAR HEARTS

Long-term Survival without Surgical Intervention

Based on analysis of a large cohort of unselected patients having functionally univentricular hearts without surgical intervention,⁶ we know that about seven-tenths of those

with a dominant left ventricle died before they reached the age of 16 years, and only half of those with a dominant right ventricle survived for 4 years after diagnosis. Congestive cardiac failure, arrhythmias, and unexplained sudden death were the leading causes for mortality in both groups. Subsequent to this, the poor outcome for these patients if not undergoing surgical palliation was confirmed by lesion specific reviews, such as that emanating from the United Kingdom.⁷ Indeed, the predicted outcome was worse than that reported from the Mayo Clinic.⁶ Some natural survivors, nonetheless, survive to adulthood, most of whom have naturally occurring lesions that balance their systemic and pulmonary circulations.^{8–10} Analysis of series of patients showed that those with such balanced circulations, providing there is good ventricular function, might survive to their seventh decade.¹¹

Long-term Management of Patients with Previous Surgery

Patients coming to attention without previous surgery usually have the balanced circulation discussed above, either because of pulmonary stenosis or some degree of pulmonary vascular disease, but necessarily are subject to the effects of chronic cyanosis, and circulations in parallel rather than series. Assuming that they are unsuitable for palliation prior to transplantation, management should be directed at minimising the repercussions in the multiple systems of the body, which we discuss briefly below.

Haematological Disorders

Erythrocytosis, iron deficiency, thromboembolism, and bleeding diatheses are all well described phenomena in adults with congenitally malformed hearts.^{12,13} The management of erythrocytosis and hyperviscosity syndrome will be discussed in detail in Chapter 61. In patients who have not had surgical palliation of their functionally univentricular heart, however, there may be physiological options to improve effective flow of blood to the lungs by judicious use of interventional techniques, such as partially relieving pulmonary stenosis, or stenting of a persistently patent arterial duct, or surgical creation of either venopulmonary anastomoses or arterial shunts, thereby reducing the stimulus to erythrocytosis. Surgery in these patients is often more complicated than expected, not only because of the tenuous circulation, and multi-system effects of chronic hypoxaemia, but also because of co-existing bleeding diatheses. These bleeding disorders include altered levels of coagulation factors in the plasma, platelet dysfunction,

and idiopathic thrombocytopaenia. The latter might be related to the degree of right-to-left shunting, and the consequent physiological exclusion of the lungs from the circulation. Subsequently, the normal fragmentation in the lungs of megakaryocytes into platelets is reduced, lowering the numbers of circulating platelets.¹⁴

Neurological Complications

The unrepaired functionally univentricular circulation of necessity produces intra- and extracardiac shunting, which exposes patients to a higher risk of paradoxical systemic and cerebral thromboembolism and abscess. This mandates the use of air filters, and vigilant attention to the presence of venous thrombosis and infection, when central or peripheral cannulation is required. Similarly, treatment of cutaneous or deep bacterial sepsis requires early aggressive antibiotic treatment.¹⁵

Gastrointestinal Complications

Hepatic, intestinal, and renal dysfunction are all common sequels of chronic cyanotic cardiac disease. Membranous glomerulosclerosis is well documented and, because of the lack of adequate resorption of uric acid, hyperuricaemia may lead to nephrolithiasis and urate nephropathy. Furthermore, hyperuricaemia is linked to rheumatological disorders, such as hypertrophic osteoarthropathy, which may be seen in up to three-tenths of patients.¹⁶ In addition, cholelithiasis is a very common finding on routine abdominal ultrasonic surveillance, with acute cholecystitis being the leading cause of non-cardiac surgical procedures in patients with Eisenmenger's syndrome.¹⁷

Non-cardiac Surgery

Non-cardiac surgery carries an increased risk in patients with unrepaired functionally univentricular hearts. Although no specific data relating to outcome is reported in the literature, those with a low pulmonary blood flow, but normal pulmonary arterial pressure, are likely to tolerate anaesthesia better than those with raised pulmonary vascular resistance. In the latter group, mortality is probably comparable with other patients having the Eisenmenger syndrome, which varies between 7% and 30%.^{17,18}

Cardiac Surgery Late in the Natural History

Survival without intervention, or only partial palliation, is well reported,¹⁹ but does not obviate the possibility of a Fontan procedure. Remarkably, the early mortality in this series of patients undergoing completion of the Fontan circulation in adulthood was just 6%, while at this time the reported overall mortality for all patients undergoing completion of the Fontan circulation at the same institution was 17%.¹⁹ A more recent study²⁰ showed similar high late mortality for adults with functionally univentricular hearts undergoing completion of the Fontan circuit to another cohort of patients with functionally univentricular hearts palliated with either an aortopulmonary shunt or a superior cavopulmonary connection. In those undergoing palliation, construction of a superior cavopulmonary shunt produced the worst outcomes. This group²⁰ concluded that completion of the Fontan circuit in adulthood, despite the lack of significant better long-term outcomes, may offer better preservation of functional state and ventricular function, and more freedom from arrhythmia, than palliation

alone. Earlier reports²¹ had reported late mortality in one-fifth of patients with functionally univentricular physiology definitively palliated by construction of a cavopulmonary shunt alone, while experience from Texas Children's Hospital²² reveals that construction of the Fontan circuit in adulthood in patients not previously undergoing a cavopulmonary shunt procedure improved the functional state of all but one of the patients. Age alone, therefore, is not a significant risk factor for poor outcomes in the contemporary era, providing that the pre-operative haemodynamics are ideal.

EARLY PALLIATIVE APPROACHES—THE PRE-FONTAN ERA

Prior to the development of the Fontan procedure, patients with functionally univentricular hearts were managed with a variety of manoeuvres to increase or reduce the flow of blood to the lungs, and to optimise systemic cardiac output. Many of these strategies are now incorporated into contemporary algorithms, but we provide a brief historical review, concentrating on the adverse consequences of long-term partial palliation.

Aortopulmonary Shunts

The advent of the Blalock-Taussig shunt revolutionised the management of patients with cyanotic cardiac disease, and those with functionally univentricular heart were no exception. Indeed, long-term survival into adult life with shunting alone is well described.²³ More recently, aortopulmonary shunts have been reserved for short-term neonatal palliation, prior to conversion to a bidirectional cavopulmonary shunt at 3 to 6 months of age. In the past, nonetheless, patients have been exposed to the whole range of arterial shunts, with all their benefits and disadvantages (Table 32-1).

Given the specific complications outlined in Table 32-1, and the generic disadvantages of a chronic volume load on the systemic ventricle, with consequent predisposition to arrhythmia, atrioventricular valvar regurgitation, and myocardial failure, few would now consider construction of a systemic-to-pulmonary arterial shunt in isolation as viable palliation for these patients. The group working at Hôpital Enfants-Malades in Paris,²⁴ nonetheless, have recently proposed a delayed strategy, not involving conversion to the Fontan circulation, but rather combining a superior cavopulmonary anastomosis with a systemic-to-pulmonary arterial shunt as definitive palliation for these patients. While the early results have been interesting, and the functional outcomes comparable to conversion to the Fontan circulation, the late results must be more uncertain. This strategy has not been widely adopted.

Banding of the Pulmonary Trunk

In patients with anatomical variants that permit unrestricted or excessive flow of blood to the lungs, progressive symptoms of congestive cardiac failure can be expected as the pulmonary vascular resistance falls in the first weeks of life. While banding of the pulmonary trunk will both protect the pulmonary vascular bed against progressive pulmonary vascular disease, and relieve the ventricle from

TABLE 32-1

SYSTEMIC ARTERIAL-TO-PULMONARY SHUNTS

Shunt Type	Anatomy	Advantage	Disadvantage
Classic Blalock-Taussig shunt	Subclavian artery to pulmonary artery on the same side	Growth of pulmonary vascular bed Increased flow commensurate with somatic growth	Frequent stenosis at level of anastomosis Poorer outcomes when performed on the same side as aortic arch
Modified Blalock Taussig shunt	Subclavian artery to pulmonary artery on the same side	Calibrated shunt appropriate for body size	Thrombosis Pulmonary arterial stenosis Reduced effective flow with somatic growth
Potts' anastomosis	Descending aorta to left pulmonary artery	Easy to accomplish	Left pulmonary arterial stenosis Risk for pulmonary over-circulation
Waterston shunt	Ascending aorta to right pulmonary artery	Easy to accomplish	Right pulmonary arterial stenosis Risk for pulmonary over-circulation

excessive volume load, it should be remembered that these patients often have co-existing anatomy that adversely affects systemic blood flow, such as a restrictive ventricular septal defect in the setting of double inlet left ventricle and discordant ventriculo-arterial connections. Under such circumstances, the effect of banding is frequently adverse in the long term, because of the development of ventricular hypertrophy, feeding a vicious cycle of an ever more restrictive obstruction to the systemic outflow tract.²⁵ Prior to the now almost uniform application of the Norwood strategy to such patients as neonates, those developing systemic obstruction subsequent to banding were treated by either direct enlargement of the interventricular communication²⁶ or a direct aortopulmonary connection.²⁷ In the rare case where banding alone was sufficient throughout infancy, there was almost inevitable progressive hypoxaemia with somatic growth. In such cases, addition of an arterial shunt or shunts, or in some institutions the construction of a classical Glenn anastomosis, was often associated with excellent outcomes in the mid-term.

The Classical Glenn Shunt

The classical Glenn shunt²⁸ is a direct anastomosis between the transected distal end of the right pulmonary artery and the superior caval vein, in either end-to-end, or end-to-side fashion, with ligation of the distal end of the caval vein. Despite excellent early results, results in the mid and late term have been disappointing, and the operation is now rarely performed. Significant numbers of patients survive, nonetheless, to require care in clinics dealing with adults having congenitally malformed hearts.

The commonest complication is the development of progressive hypoxaemia, resulting from intrapulmonary shunting as a result of the development of pulmonary arterio-venous malformations. Their exact prevalence varies depending on the mode of investigation, but they are found in between one-quarter and three-fifths of patients. Their cause remains fully to be elucidated, but clearly is related in some way to the lack of direct exposure of the lungs to an unknown hepatic factor. Restoration of hepatic flow to the lungs, by either aortopulmonary shunting or completion of the Fontan circuit, has widely been reported to reduce intrapulmonary shunting, and improve cyanosis, within a few weeks of the procedure.

Alternative strategies include embolic occlusion, but this is appropriate only for those with focal abnormalities, a relative rarity. Although many patients have been successfully palliated for many years by the classical Glenn anastomosis, the introduction of the bidirectional superior cavopulmonary anastomosis has largely obviated its use.

FROM GLENN TO FONTAN, AND CONTEMPORARY STRATEGIES FOR MANAGEMENT

The success of the classical Glenn procedure described previously was a tantalising stimulus to complete exclusion of a ventricle on the right side of the circulation.²⁹ Various iterations of veno- and atriopulmonary anastomoses were tried, and often failed, prior to the seminal work published in 1971.³⁰ While early animal experiments had shown good tolerance when the right atrium was anastomosed to the pulmonary artery with closure of the pulmonary valve, the results were uniformly fatal when the right ventricle was completely disconnected. The scene was set for complete exclusion of the right side of the heart; long-term survival was achieved in animals with the superior caval vein anastomosed to the right upper pulmonary artery, later combined with connection of the inferior caval vein to the left atrium.²⁹

The Fontan Procedure

The original report of the Fontan circulation was based on total exclusion of the right side of the heart in three patients, aged 12, 36 and 23 years respectively.³⁰ Although Fontan and his colleagues initially placed homograft aortic valves into the atriopulmonary connection, and into the inferior caval vein, it rapidly became apparent that this was an unnecessary addition to the procedure.³¹ Indeed, following the initial report, there was a remarkably rapid evolution of operative variants (Table 32-2),³²⁻⁴⁰ criteria for exclusion, and haemodynamic requirements, the essence of which we outline next.

Modifications of the Fontan Procedure

Despite all the modifications described above, the generic term Fontan circulation remains as a unifying description of

those patients in whom circulations have been established in series without the inclusion of a subpulmonary ventricle. Each iteration has been associated with its own advantages and disadvantages, and the results of each variant, in terms of specific complications and outcomes, should be assessed separately. All of these efforts have culminated in a staged strategy of palliation, often starting with aggressive management of potentially adverse haemodynamics in the early neonatal period.

Contemporary Strategies and Outcomes

The contemporary strategy for managing patients with functionally univentricular hearts is a staged process designed to obviate obstruction to systemic outflow, and minimise the amount and duration of volume loading of the systemic ventricle. The type of early neonatal palliation will vary depending on the underlying anatomy, but the aim is to optimise haemodynamics towards the construction of a bidirectional cavopulmonary anastomosis at the age of from 3 to 6 months, and completion of a total cavopulmonary anastomosis in the second or third year of life. This strategy has resulted in far superior results compared with those achieved even a decade previously, and the benefits have clearly been multi-factorial. Improved early

palliation, particularly for those with hypoplastic left-sided heart syndrome, which is now the commonest anatomical subtype progressing to palliation with the Fontan circuit, and the introduction of the bidirectional cavopulmonary anastomosis as an interim step prior to completion of a Fontan circulation, must represent two of the most important advances in the field since the original successful clinical application.³⁰

Long-term Outcomes of the Completed Fontan Circulation

The results of the allegedly perfect Fontan procedure were analysed in a large series of patients.⁴¹ Most of these patients, however, had undergone surgery prior to routine interim staging using a bidirectional superior cavopulmonary anastomosis. The investigators predicted survival under optimal conditions of 92%, 89%, 88%, 86%, 81% and 73% at the age of 1 month, 6 months and 1, 5, 10 and 15 years, respectively, highlighting the late attrition that appears inevitable with this flawed circulation. With improved strategies, however, come improved results. Thus, survival of 91% at 10 years is now reported in patients with lateral tunnels,⁴² and overall mortality rate of 2.8% for one cohort of patients.⁴³ Overall early mortality rate was

2.8%. Others⁴⁴ have reported overall survival rate of 85% at 15 years, albeit with an incidence of major co-morbidities, such as arrhythmias in one-tenth, and other complications, such as obstruction of the extracardiac conduit or left pulmonary artery, ventricular failure, and protein losing enteropathy bringing the onset of problems in up to almost one-quarter of the patients. A further analysis⁴⁵ of over 300 patients showed an overall survival at 24 years of 84%. Survival was lower for those with an atriopulmonary connection compared to a lateral tunnel. Arrhythmias and failure were also less frequent in those having a lateral tunnel. Since the introduction of extracardiac conduits in 1990, mortality has been zero in this group, and there have been no sustained arrhythmias or failure. The authors⁴⁵ concluded that, with improvement of surgical techniques, and careful selection of patients, the hospital mortality, as well as the rates of complications, will be lower, or at least deferred, in those operated in the modern era.⁴⁶ Even so, the Fontan circulation, and its physiological consequences remain as a unique experiment that remains to be fully understood, both in terms of its optimal performance, and its modes of failure.

THE PHYSIOLOGY OF THE FONTAN CIRCULATION AND ITS FAILURE

Basic Principles

Regardless of the exact nature of the connections, the completed circulation is often described as one having a single energy source, namely the dominant ventricle driving the systemic circulation. This energy is dissipated through a series of resistors. The first is in the ventricle itself, and is related to diastolic function, with others provided by the systemic vascular bed, the systemic venous bed, and the pulmonary vascular bed. It is now apparent that there are additional sources of energy, and potentially additional sources of dissipation of energy. All of these are modified by time. Each element of the Fontan circulation is abnormal and while the circulation must be considered as a whole, we analyse here the contribution and adverse effects of each.

The Ventricle

Debate continues as to whether ventricular morphology has a significant impact on the efficiency and outcomes of the Fontan circulation. This is increasingly pertinent given the improved survival of patients with hypoplastic left-sided heart syndromes. There can be no doubt that there are inherent differences between the architecture, atrio-ventricular valvar morphology, and functional responses when either the left or right ventricle is dominant in these patients, and virtually no attention has been paid to the truly univentricular arrangement. If the dominant left ventricle is compared between patients having tricuspid atresia and double inlet left ventricle,⁴⁷ differences between the groups are difficult to discern in terms of early geometric adaptation and outcomes of the Fontan operation. Similarly, little evidence exists to differentiate between those with dominant right or left ventricles. Indeed, in one large study, a systemic right ventricle was shown not to influence early outcomes,⁴⁸ and in another, those with dominant right

ventricles had superior survival to, albeit more complex, patients with a dominant left ventricle.⁴⁹

At the time of the bidirectional Glenn procedure, or at the time of completion of the Fontan circuit if no bidirectional Glenn procedure has been performed previously, there is usually a marked decrease in the preload to the dominant ventricle. The degree of reduction primarily depends on the prior ratio of pulmonary-to-systemic flows, which often exceeds 2:1. It is, of course, the reduction of preload, and hence ventricular dilation and work, which provides much of the reason for undertaking the operations themselves. While few would disagree that reduction of systemic ventricular volume load is generally beneficial, it does come at a price when completing the Fontan circulation.

Prior to construction of the Fontan circuit, abnormal systolic ventricular performance is rarely a major problem, and is sustained or improved in most after completion of the circuit. In an elegant study from Boston's Children's Hospital,⁵⁰ it was shown that restoration of normal systolic ventricular mural stress was achieved in most individuals undergoing a Fontan procedure prior to the age of 10 years, an important feature when examining the potential effects of volume unloading of the systemic ventricle. The law of preservation of mass predicts that, given a marked reduction in ventricular preload, preserved shortening and constant mural mass, there must be a resulting increase in mural thickness. This was shown experimentally,⁵¹ and demonstrated clinically in children undergoing the Fontan operation in the 1990s.⁵² The implications of this increased mural thickness are, perhaps, not intuitive. It might be reasonable to think that this increased thickness would modify the properties of end-diastolic compliance, and hence mural stiffness. There is very little evidence for this. Rather, the evidence points to abnormalities of early relaxation as being the major result. We have shown that prolongation of the time constant of early relaxation, known as tau, and the isovolumic relaxation time, are both inversely related to the characteristically reduced early rapid filling.^{52,53} Consequently, much of diastolic filling is dependent on atrial systole. Very recently, this early diastolic dysfunction, also demonstrable after bidirectional Glenn procedures, was shown to impact negatively on recovery after subsequent conversion to the Fontan circuit,⁵⁴ and may also be important in the late follow-up of these patients (see later discussion).

This incoordinate relaxation is a feature of hearts affected by hypertrophy, ischaemia, and abnormal mural motion, all of which may exist in the ventricular myocardium of patients converted to the Fontan circulation. It is the adverse effect of abnormalities of mural motion, nonetheless, that appears to predominate. Using both direct angiographic analysis,⁵⁵ and surrogate measurements by Doppler echocardiography,⁵⁶ we have been able to show that abnormalities in base-to-apex mural motion are mirrored by abnormal flow from base to apex during isovolumic relaxation of these ventricles. These abnormalities persist at mid-term follow-up, but interestingly, late diastolic abnormalities, characteristic of worsening ventricular compliance, also become apparent at this time.⁵⁷ The combination of persistently abnormal early relaxation with worsening ventricular compliance is particularly malignant, markedly reducing the ability of these ventricles to fill, potentially reducing the flow of blood to the lungs, or at least leading to elevated pulmonary arterial

pressure. The changes may also account for some of the late failure seen in these patients. There is little that can be done therapeutically to avoid the early diastolic abnormalities, and they may indeed worsen naturally with age, as in the normal heart.⁵⁸ Avoidance of those factors known to lead to worsening compliance, nonetheless, such as persistent obstruction of the left ventricular outflow tract or hypertension, is of fundamental importance.

While diastolic abnormalities predominate early-on, there is no doubt that systolic failure also becomes apparent in some patients late after the procedure. This may be a reflection of abnormal vascular properties, of ventricular vascular interactions (see below), or maybe intrinsic to the previously stressed or damaged myocardium itself. We,⁵⁹ and others,⁶⁰ have recently shown abnormal myocardial force frequency relationships in these patients, probably reflecting abnormal handling of calcium by the myocardium. Although abnormal, the changes seen are not at the level seen in adults with end-stage cardiac failure secondary to dilated cardiomyopathy.⁶¹ Although a similar degree of physical incapacity may exist, with similar degrees of elevation of neurohormonal markers,⁶² the successful response to pharmacological interventions noted in those with dilated cardiomyopathy remains to be adequately addressed in patients with the Fontan circulation. As will be demonstrated later, sometimes the response of those with the Fontan circulation is counter-intuitive to the concepts established in cardiac failure due to other causes.

Although difficult to prove, it is likely that staged transition to the Fontan circulation has contributed significantly to the overall improvements in outcome for these patients. Avoidance of excessive early volume loading, avoidance of excessive myocardial hypertrophy, and therefore avoidance of the major geometric changes discussed previously, would all seem conceptually beneficial. For the long-term outcome of these patients, avoidance of the age-related naturally occurring changes in late diastolic performance, particularly in relation to the changes in compliance seen with ageing, hypertension, and so on, may be the next frontier for maintenance of myocardial performance.

The Systemic Vascular Bed, and Ventricular–Vascular Coupling

Elevated systemic vascular resistance is well recognised after conversion to the Fontan circulation.^{63,64} How much of this is related primarily to the intrinsically low resting cardiac output, and how much is secondary to circulating vasoconstrictors, and so on, has not been fully elucidated. The impact of this elevation of systemic vascular resistance on ventricular–vascular coupling also remains fully to be elucidated. When control patients, and others with a Blalock-Taussig shunt, were compared to those with the Fontan circuit, the relationship between cardiac index and vascular impedance, at baseline and with dobutamine, was highly abnormal in the Fontan group.⁶⁴ Careful analysis of this data, with the relationship between cardiac index and impedance being almost flat in those with a Fontan circuit, suggests that simply changing impedance may not necessarily lead to an improved cardiac index. This is crucial when considering the potential role for vasodilation in these patients.

It would appear intuitive that, in these patients with markedly elevated systemic vascular resistance and abnormal ventricular–vascular coupling, vasodilation would improve their circulatory performance. This would only be the case if the abnormal vascular characteristics were of primary importance, rather than a secondary phenomenon. Randomised double-blind, placebo-controlled studies of therapeutic intervention in the setting of congenital cardiac disease are a rarity, but such data is available for the inhibition of angiotensin converting enzyme in patients with the Fontan circulation.⁶⁵ Enalapril or placebo was given in crossover fashion. Overall, there was no change in Doppler echo characteristics, and a tendency to worse exercise performance. Indeed, there was reduced incremental cardiac index during exercise in the patients receiving enalapril. Despite this data, many physicians continue to give drugs to inhibit the angiotensin converting enzyme, presumably in the hope of a beneficial effect when given chronically. It is possible, but unproven, that there are subgroups, such as those with severe systolic dysfunction or atrioventricular valvar regurgitation, that may benefit. It is also possible to put forward theoretical arguments for the use of inhibitors with tissue-inhibitory properties, such as quinapril or ramapril, in order to avoid the adverse remodelling described above. Irrespective of the attraction of the theories, there is presently no evidence for this therapy being beneficial in these patients.

The Veno-pulmonary Circuit

There has been a major evolution in the design of the haemodynamics in the Fontan circuit since its inception. As already discussed, the initial connection from right atrium to pulmonary arteries has been abandoned in favor of more streamlined versions. The benefits of such modifications have been confirmed experimentally and clinically. When comparing contemporaneously treated patients undergoing either an atriopulmonary connection or construction of a lateral tunnel,⁶⁶ no difference was noted between the groups at rest, although cardiac output in both was significantly lower than in normal controls. Cardiac output was higher, however, in those with a lateral tunnel at low and moderate workloads, as was the rate of respiration. Despite a similar production of carbon dioxide, and similar minute ventilation, those with a lateral tunnel were taking more frequent, smaller, breaths during exercise. We speculated that these patients were harnessing the beneficial effects of the work of breathing on the pulmonary circulation, this being a particularly prominent feature in patients with veno-pulmonary connections.

Indeed, the work of breathing is a significant additional source of energy for the circulation in these patients. Normal inspiration at negative pressures has been shown to increase the flow of blood to the lungs after the Kawashima operation,⁶⁷ those with an atriopulmonary connection,⁶⁸ and in patients after the total cavopulmonary connection.⁶⁷ Using magnetic resonance imaging to measure flow, it has been shown that approximately one-third of the cardiac output can be directly attributed to the work of breathing in patients after a total cavopulmonary connection.⁶⁹ Regional properties of subdiaphragmatic venous flow are fascinating in these patients.⁷⁰ While portal venous flow is markedly abnormal after the Fontan operation, the respiratory

influence is relatively limited. Inferior caval venous flow does vary with respiration, but in a relatively normal fashion. It is the hepatic venous flow that differentiates these patients from their normal counterparts. There is a very marked influence of respiration on total hepatic venous flow. Inspiration, presumably by a dual effect on venous pressure and compression of the liver by diaphragmatic descent, markedly augments hepatic venous contribution to the total venous return. The liver appears to act as a sump of blood, which can be drawn upon during inspiration.

The converse is true when considering positive pressure ventilation. It has long been known that increasing levels of positive end-expiratory pressure, during positive pressure ventilation, has adverse effects on the Fontan circulation.⁷¹ We have learnt over the years that early post-operative restoration of normal negative pressure ventilation can be beneficial in these patients. We investigated this experimentally in children after the Fontan operation, comparing the effects of a negative pressure cuirass device with standard positive pressure ventilation.⁷² By mimicking the normal action of breathing, negative pressure ventilation, when compared to positive pressure, led to an average increase in cardiac index of approximately two-fifths. While not advocated as a routine clinical tool, although sometimes very useful therapeutically, this data heightens our awareness of the relationship between mean airway pressure and cardiac index in these patients. The available data suggests an approximately linear relationship between the two. Thus, the higher the mean airway pressure, the lower is the cardiac index. Management of these patients, therefore, should be directed towards minimising mean airway pressure when they are being ventilated for cardiac and non-cardiac procedures. This can be achieved by minimising plateau pressures, end-expiratory pressures, and rate of rise of pressure. The patients should be maintained with the minimum mean airway pressure compatible with normal oxygenation, avoiding any collapse of the airway or similar complication, and achieving adequate alveolar ventilation to ensure normal partial pressures of carbon dioxide.

The Pulmonary Vascular Bed

A low pulmonary vascular resistance is a prerequisite for early success after completion of the Fontan circuit. The lower the total pulmonary resistance, which incorporates the pulmonary vascular resistance, pulmonary venous resistance and left atrial resistance, the better the end result. We have already discussed the influence of abnormal ventricular responses to potentially raised left atrial pressure, and therefore left atrial resistance. Structural pulmonary venous abnormalities are also important. Naturally occurring pulmonary venous stenosis may occur in many of the disease substrates that necessitate the Fontan circulation, such as those with isomerism of the right atrial appendages, or may evolve as a result of abnormal haemodynamics after, for example, an atriopulmonary anastomosis. In the latter case, gross enlargement of the right atrium may compress the adjacent pulmonary veins as they return to the left atrium.⁷³ This complication should always be excluded in patients with worsening functional performance late after these operations. Less well characterised is the chronic effect of the Fontan circulation on pulmonary arterial resistance. Pulmonary thrombo-embolism is not infrequent,⁷⁴

may be covert,⁷⁵ and clearly will lead to adverse changes in vascular resistance. Abnormalities of arteriolar resistance adversely influence early outcome, in terms of both morbidity and mortality,^{76,77} but there is little data available regarding the long-term effects of the Fontan circulation on the pulmonary vascular bed.

COMPLICATIONS OF THE FONTAN CIRCULATION AND THEIR MANAGEMENT

Although there is ample evidence for improved mid-term results as a result of improvements in early palliation, operative techniques, and in the design of the Fontan circuit itself, as we have discussed, the nature of Fontan physiology is intrinsically flawed, and the circuit is likely to fail earlier than its normal biventricular counterpart. Furthermore, there are large numbers of patients surviving into adult life having been treated in an earlier era with less advantageous surgical algorithms. Because of the increasing survival of patients with the hypoplastic left heart syndrome, management of the late complications of the Fontan circulation, and ultimately its failure, is likely to become a larger issue, rather than a diminishing burden, to those specialising in the future in the treatment of those with congenitally malformed hearts. Although often forming a constellation of inter-related co-morbidities, it is convenient to discuss separately the modes of failure.

Arrhythmias

Sinus nodal dysfunction occurs in up to one-sixth of patients after conversion to the Fontan circuit, and increases with time of follow-up.⁷⁸ Among other reported arrhythmias, re-entry atrial tachyarrhythmias are the commonest, and are often associated with haemodynamic deterioration, either causally or as a result.⁷⁹ All patients with new arrhythmias should undergo full haemodynamic assessment in order to exclude important anatomical or functional substrates for the abnormal rhythms. If present, haemodynamic abnormalities should be treated aggressively. Specific treatment of the arrhythmias remains challenging. They are difficult to control pharmacologically, and although contemporary three-dimensional mapping systems and catheter ablation may provide immediate relief in up to four-fifths, persistent arrhythmias,⁸⁰ or recurrent or new atrial arrhythmias are frequent. For that reason, those with persistent or recurrent atrial arrhythmia may be candidates for a conversion of the circuit combined with arrhythmic surgery,⁸¹ as we discuss later.

Hepatic Dysfunction and Thrombo-embolic Events

The patients are at high risk for thrombo-embolic events. In addition to the obvious risk from sustained atrial arrhythmias, the low flow in the distended pathways, abnormal ventricular anatomy, the use of intravascular prosthetic material, and impaired hepatic function all contribute to the elevated risk for thrombo-embolism. Abnormal coagulative factors have been shown before and after completion of the Fontan circuit.⁸² Optimal management of such changes, also reported by others, remains to be defined. Although anatomical and haemodynamic abnormalities

are clearly responsible for some events, the effect of co-existing hepatic dysfunction cannot be ignored. Increased activity of platelets,⁸³ as well as persistent thrombocytopenia,⁸⁴ has also been reported. The cause of hepatic dysfunction, and even frank cirrhotic changes, remains poorly understood, but presumably relates in some way to chronic elevation of hepatic venous and portal venous pressures. As with atrial arrhythmias, new onset thrombo-embolic symptoms require full haemodynamic re-evaluation to exclude, and potentially treat, any anatomical and functional substrates. Most would consider anti-coagulation to be indicated in those with a documented and clinically significant thrombo-embolic event, but the use of prophylactic anti-coagulation or anti-platelet therapy remains a subject of continuing debate.^{85–88} Those reviewing thrombo-embolic outcomes⁸⁹ found a high incidence of thrombo-embolic events within the first year after surgery, and then again with a second peak beyond 10 years, with the lowest incidence in those receiving coumadin. A similar study, however, showed no differences between patients receiving no medication, aspirin, or coumadin.⁹⁰ Furthermore, the overall incidence of thrombo-embolic events was remarkably lower in the latter study, leading the authors to speculate that ethnic differences may exist in regard to this complication. These data are far from definitive, and therapeutic policies vary from unit to unit, and even within units! This issue will not be resolved in the absence of a long-term randomised clinical trial.

Cyanosis

Most patients, in the absence of a fenestration, will have arterial saturations in excess of 90%. Unexpected desaturation, either at rest or on exercise, should prompt surveillance for abnormal systemic venous connections to the left heart, or the development of pulmonary arterio-venous fistulas. The question as to whether, in the long term, the presence of a fenestration might reduce the incidence of complications associated with venous hypertension, at the cost of chronic cyanosis and right-to-left shunting, remains unanswered. In one study of patients followed for 10 years after closure of their fenestration, there was improved oxygenation, reduced need for anti-congestive medication, and improved somatic growth, with minimal instances of death or haemodynamic decompensation.⁹¹ Thus, most would consider persistent resting desaturation below 90% to 95% as an indication for investigation and treatment, if the haemodynamics allow.

Exercise Intolerance

Abnormalities of exercise function are ubiquitous. Their cause and effect, however, is less well understood. Overall, the patients demonstrate reduced responses to workload and cardiac output, increased ventilation, and decreased anaerobic threshold and consumption of oxygen, in addition to chronotropic incompetence. Those with atrio-pulmonary connections fare less well than those with intra- or extracardiac conduits, but multiple additional factors, such as era of operation, ventricular function, number of operations, and so on, contribute to ultimate performance. There also appear to be significant non-physical constraints. We recently reported reduced levels of the physical activity in

patients having an overly protective social environment, consequent upon adverse perception by both the patients and their parents of the risks and benefits of exercise. Exercise testing, nonetheless, is useful for longitudinal follow-up. Any significant deterioration should be a stimulus for detailed anatomical and functional surveillance to establish for possible causes of circulatory impairment.

Protein Losing Enteropathy

One of the most severe manifestations of the failing Fontan circulation is protein losing enteropathy. Chronic loss of protein into the gastrointestinal tract leads to hypoalbuminaemia, effusions, ascites, oedema, and ultimately muscle wasting and cachexia. The underlying pathogenesis remains to be fully explained, but its development in the absence of a major, treatable, haemodynamic disturbance carries an extremely poor prognosis. Only half the patients with generalised oedema are alive after 5 years.⁹² The reported incidence varies depending on era and cohort, but in one review it was present in 4% of patients at an average of 6.9 years after completion of the Fontan circuit.⁹³ Diagnosis relies on the demonstration of hypoalbuminaemia in the presence of increased faecal loss of protein. The latter is usually measured as increased levels of α_1 -antitrypsin in the faeces, but it should be remembered that elevated levels may occur in the absence of overt loss of protein. As with all other late complications of the Fontan circulation, diagnosis of the complication should prompt a vigilant anatomical and haemodynamic evaluation for correctable abnormalities.

In the absence of an overtly treatable cause, careful attention to diet, fluid balance, and the judicious use of diuretics and infusions of protein may all provide symptomatic relief. Although there are many reports of individual patients, and small case series, purporting to show benefit from various therapeutic strategies, no single intervention can be considered to be of uniformly proven benefit. Apparent improvement has been described in those receiving steroids, high molecular weight heparin treatment, sildenafil, octreotide, atrioventricular synchronous and biventricular pacing, and after fenestration of the circuit. Successful reversal following revision of the circuit has also been described,⁹⁴ particularly if attempted in an early stage.^{92,95,96} As we discuss later, resolution is almost invariably in survivors after cardiac transplantation.

Plastic Bronchitis

Plastic bronchitis is a rare and potentially fatal complication after completion of the Fontan circulation.^{97,98} It manifests clinically by expectoration of long, branching, bronchial casts with recurrent life-threatening obstruction of the airways (Fig. 32-1). Its pathogenesis is still not entirely clear, but elevated pulmonary and central venous pressures have been implicated, along with endobronchial lymphatic leakage. The complication can occur in the early post-surgical period after creation of the Fontan circuit, or as a late complication in the patient with a failing Fontan circulation, often together with protein losing enteropathy.⁹⁹ Symptoms of acute respiratory distress, and cough producing pearly white bronchial casts, without signs of acute inflammation or acute cardiac failure, should suggest the diagnosis.

Figure 32-1 Bronchial cast.

The standard treatment involves strategies designed for both the short and long term. Immediate treatment is targeted at resolving the obstruction in the airways. Chest physiotherapy, mucolytics and in severe cases bronchoscopy are accepted options to remove the casts. Aerosolised urokinase, or r-TPA, are other medical options, but should be used carefully in the early post-surgical course.^{100,101}

Treatment over the long term aims to lower the pulmonary and central venous pressures. In patients in the early period, enlargement or reopening of a fenestration, or creation of a fenestration,¹⁰² should be considered. Atrial and ventricular arrhythmias need to be ruled out,¹⁰³ along with failure of the systemic ventricle due to the increased volume load. Successful use of drugs to reverse pulmonary hypertension, such as treatment with sildenafil or an endothelin-1 antagonists,^{104,105} has been reported. In patients with a generalised failure of their Fontan circulation, management is based on the severity of the presentation and the existence of additional clinical features, such as protein losing enteropathy. It might, therefore, additionally involve the various medical approaches already discussed,^{99,106,107} as well as the surgical options to be reviewed in the sections that follow.¹⁰⁸

Surgical Management of the Failing Patient

Revision of the Circuit

The aims of conversion of the circuit are to improve haemodynamic efficiency, address atrial arrhythmias, and improve functional capacity. To that end, those with either an atriopulmonary connection or a lateral tunnel have it replaced by an extracardiac conduit, and right- and left-sided Maze procedures are performed, usually with coincident insertion of an epicardial, anti-tachycardia, pacemaker in patients with atrial flutter or fibrillation.^{81,109} A right atrial maze is usually incorporated irrespective of symptoms, but in patients free of documented atrial arrhythmias, the left-sided Maze procedure is not recommended owing to the longer ischaemic time required for the combined procedure.

A group from Children's Memorial Hospital in Chicago has championed revision of the circuit as a therapy for late failure.¹¹⁰ Mortality in a series of over 100 patients was only

0.9%, a quite remarkable achievement, not consistently reproduced in other series. The overall incidence of recurrent arrhythmia was 12.8% during a mean period of follow-up of almost 5 years. They concluded that conversion combined with arrhythmic surgery is a procedure with low surgical risk, and relatively low risk of recurrence of tachycardia, and which provides marked improvement in the functional state of most patients. Selection, and stratification of risk, of the patients, however, is not well defined. It remains the case that for some patients with late failure, cardiac transplantation may be the only viable therapeutic option.

Cardiac Transplantation after Fontan Palliation

Despite the excellent results reported for conversion of the circuit, not all patients are suitable, and others continue to experience significant symptoms, or deteriorate, after conversion. Cardiac transplantation may be the only option for such patients. Earlier reports suggested a prohibitively high mortality, but more recent series report rates of death from 2.4% to 6.7%.^{81,111} Symptomatic improvement is almost uniformly observed in survivors.¹¹²

Based on their experience, the group from Padova¹¹² recommended that cardiac transplantation should be considered in the decision-making process for adult patients at high risk as an alternative to completion of the Fontan circuit. This is supported by two additional recent studies.^{113,114} Of particular note was the complete resolution of protein losing enteropathy in the survivors, with the group as a whole having marked improvement in symptoms and functional capacity.¹¹⁴

CONCLUSIONS

The understanding of the functionally univentricular circulation and its management has improved markedly over the past three decades. Although improved early palliative strategies have led to improved early and mid-term results, failure of the circuit is the likely outcome for most patients at some stage in their late follow-up. Strategies to avoid, defer, and treat such failure continue to be developed.

This article is an excellent review of contemporary outcomes of heart transplantation as ultimate palliation of the failing Fontan circulation. Resolution of protein-losing enteropathy, and improved functional performance, was uniform in those who survived the early post-operative period.

Straddling Atrioventricular Valves

MICHAEL L. RIGBY and ROBERT H. ANDERSON

The entities to be considered in this chapter differ from all those others considered in this section of our book devoted to specific lesions. This is because hearts with straddling and overriding atrioventricular valves represent a series of anatomical stages between the extremes of double inlet and biventricular atrioventricular connections. As such, therefore, straddling and overriding can involve the right or left atrioventricular valve, or a common atrioventricular valve, in the setting of either double inlet right or double inlet left ventricle. The other end of these various spectrums will then depend upon the particular valve involved, and on the topological arrangement of the ventricular mass. The structure of the individual heart itself will reflect the precise degree of straddling, as opposed to overriding of the valvar structures. Because of this, it is not possible to approach the lesions in the same fashion as all others discussed in this section of our book. The clinical features will not only reflect the variations already discussed above, but will also differ markedly according to the specific ventriculo-arterial connections present, and the associated malformations. The understanding of the malformations, and their correct diagnosis, depends on a thorough appreciation of their anatomical features. In this chapter, therefore, we describe the different patterns on the basis of their structure. This in itself requires that we define precisely our understanding of the nature of straddling and overriding, since the definition of these features, and the way in which they are described, has varied markedly.

DEFINITIONS

In the normally structured heart, each ventricle, which functions as the muscular pump driving its circulation, has competent valves guarding its inlet and its outlet. The functional components of these valves are the leaflets. Of necessity, if the heart is normal, these leaflets are attached exclusively within their own ventricle. There are subtle differences between the nature of the valvar attachments which are not strictly relevant to this chapter, but worthy of emphasis. Thus, the leaflets of the atrioventricular valves are normally attached in annular fashion, and their line of attachment is coincident with the anatomical atrioventricular junction (Fig. 33-1). The leaflets of the arterial valves, in contrast, are attached in semilunar fashion, with their line of attachment crossing the anatomical ventriculo-arterial junction (Fig. 33-2). Much more significant from the stance of our definitions for straddling and overriding is the nature of the free edge of the valvar leaflets. The atrioventricular valves close against the full force of ventricular systole. So as to retain valvar competence, therefore, the free edges of

the leaflets are furnished with tension apparatus (see Fig. 33-1). In the normal ventricles, the entire tension apparatus for each valve, like the attachments of the leaflets at the atrioventricular junctions, is exclusively contained within its own ventricle. The arterial valves, in contrast, close in ventricular diastole. It is the force of the column of blood supported by the leaflets which ensures their competence. Arterial valves, therefore, lack any tension apparatus.

When hearts are congenitally malformed, either the atrioventricular or the ventriculo-arterial junctions, or on occasion both junctions, can be shared between the ventricles. It is the sharing of an atrioventricular junction between the ventricles that is usually the essential feature of the entities to be discussed in this chapter. In the abnormal hearts to be discussed, it is also the case that, in the majority of cases, the tension apparatus is attached not in one, but in both of the ventricles. In order to distinguish between the sharing of the junctions, and the abnormal location of the tension apparatus, and to produce a terminology which is applicable to both atrioventricular and ventriculo-arterial valves, we define separately the nature of these two independent features.¹

Overriding, therefore, describes the situation in which a junction, either atrioventricular (Fig. 33-3) or ventriculo-arterial (Fig. 33-4), is shared between the ventricles. This permits us to reserve straddling to describe the arrangement in which the valvar tension apparatus is attached to either

Figure 33-1 The left atrioventricular junction of a normal heart has been opened inferiorly by a cut parallel to the atrial septum, and the junction spread to show the attachments of the leaflets of the mitral valve. The hinges of the leaflets are arranged in annular fashion (purple dotted line), and along the mural leaflet the line corresponds to the atrioventricular junction. Note that the free edges of the leaflets are tethered by the tendinous cords to the papillary muscles within the left ventricle.

Figure 33-2 The ventriculo-pulmonary junction of a normal heart has been opened anteriorly, and the junction spread to reveal the arrangement of attachment of the leaflets of the pulmonary valve, the leaflets themselves having been removed. The hinges of the leaflets are semilunar (purple dotted line), and cross the anatomical ventriculo-arterial junction between the muscular infundibulum and the fibrocollagenous wall of the pulmonary trunk (yellow dotted line). Unlike the atrioventricular valves, the arterial valves lack tension apparatus.

Figure 33-3 The picture of a straddling tricuspid valve in a patient with concordant atrioventricular connections shows how, almost always in this situation, the atrioventricular junction is shared between the ventricles, the right atrium connecting directly with the left and the right ventricular chambers.

side of the ventricular septum and, hence, tethers the valvar leaflets in both ventricles (Fig. 33-5). Using these definitions, it follows that an atrioventricular valve can straddle and override. Such an arrangement (Fig. 33-6) is by far the commonest encountered. But it is also possible for an atrioventricular valve to straddle without overriding (Fig. 33-7), or to override in the absence of straddling of the tensor apparatus (Fig. 33-8). It also follows that, within our definitions, it is possible for an arterial valve to override,

Figure 33-4 The picture shows a simulated four-chamber echocardiographic section in a heart with tetralogy of Fallot. The orifice of the aortic valve overrides the crest of the ventricular septum (star) so that both the right and left ventricles communicate directly with the aorta (arrows).

but not to straddle, since arterial valves lack any tension apparatus.

These chosen definitions have major implications for the description of other features of the hearts that are malformed because they contain straddling and overriding atrioventricular valves. The degree of overriding of the abnormal valve determines the precise atrioventricular connections, which can vary from double inlet to concordant or discordant. A spectrum exists between these extremes. There are two ways of coping with this situation. One way is to consider straddling in itself as a special case. The second approach is to emphasise the effect of the degree of override on the atrioventricular connection, dividing the spectrum at its midpoint when categorising the segmental arrangement (see Chapter 1). Thus, considering as an example the spectrum of straddling of the tricuspid valve, as illustrated in Figure 33-3, the hearts containing the straddling valve can be categorised as exhibiting either double inlet ventricle or concordant atrioventricular connections, depending of the proportion of the overriding junction supported within the right as opposed to the left ventricles. This is the principle used throughout this chapter. In the past, it was much easier to divide this spectrum in theory than it was in practise. The development of tomographic diagnostic techniques, and the ability to reconstruct individual anatomy in three dimensions, now means that it is possible also to make these distinctions in the clinical setting.

It was also the case that, when we first used this 50% rule for the purpose of assigning patients with straddling valves as having double inlet or biventricular atrioventricular connections, we had problems in moving from 49% to 51%. This was because, depending on our decision, a

Figure 33-5 This simulated four-chamber echocardiographic section is from a patient with double outlet right ventricle and straddling mitral valve. It shows how, in addition to overriding of the left atrioventricular junction, the tension apparatus of the mitral valve (arrows) is attached to both the right and left ventricular sides of the ventricular septum (star). It is the abnormal attachment of the tension apparatus that we describe as straddling.

Figure 33-6 The cartoon illustrates overriding of the mitral valvar annulus (red bracket) and straddling of the tension apparatus (arrows) relative to the muscular ventricular septum (purple).

patient considered to have a biventricular heart in the setting of biventricular connections would suddenly possess a univentricular heart if we designated the connection as double inlet. At that time, we were also promoting the concept of univentricular hearts as discrete from hearts with two ventricles, illogically disqualifying as ventricles all those chambers which lacked an inlet component or,

Figure 33-7 The cartoon, again illustrating the mitral valve, shows overriding, with the valvar orifice supported within both ventricles (bracket), but no straddling, all the tension apparatus being contained within the left ventricle.

Figure 33-8 This cartoon (compare with Figs. 33-6 and 33-7) shows straddling of the mitral valve, but no overriding, all of the orifice of the valve being supported within the right ventricle (bracket).

more specifically, half an inlet component.² Once the lack of logic in this approach was identified,³ and we realised that it was the atrioventricular connection, rather than the ventricular mass, which was effectively biventricular or univentricular, then the semantic problems disappeared.⁴ The procedural problems, nonetheless, remain. It is still difficult precisely to adjudicate between 49% and 51% of overriding of an atrioventricular junction. Since the decision will no longer affect the description of the ventricles, the distinction loses much of its force. As we will see, in clinical practise it is more important in this setting to describe

Figure 33-9 This anatomical section, in four-chamber plane, shows the essence of a uniatral but biventricular atrioventricular (AV), here due to absence of the left atrioventricular connection (green dotted lines) and straddling of the crest of the ventricular septum (star) by the right atrioventricular valve (arrows) in the setting of right hand ventricular topology. Note that the atrial septum walls off the left atrium from the atrioventricular junction.

the size of the ventricles. While this, to some extent, reflects the precise atrioventricular connection, it is certainly not the only determining feature. The degree of override, therefore, is determined with as much accuracy as is possible, dividing the spectrum on the basis of the proportion of the overriding junction attached within the two ventricles relative to the location of the ventricular septum (see Fig. 33-3).

There is then a second major point to consider in terms of definitions. This is when the valve which straddles and overrides is guarding a common atrioventricular junction, rather than a separate right or left atrioventricular junction. The first problem here is in defining a common atrioventricular junction, and distinguishing the common junction from the arrangement seen when one atrioventricular connection is absent and the other junction is itself straddling and overriding (Fig. 33-9). We use the atrial septum as our defining feature. We define a common atrioventricular junction as one which is common to both atriums and both ventricles, although the sharing of this junction does not have to be uniform between the four chambers. The exemplar of hearts with such a common junction is the entity usually described simply as an atrioventricular septal defect (see Chapter 27). In these hearts, the presence of the septal defect between the leading edge of the atrial septum, and the crest of the ventricular septum

Figure 33-10 This four-chamber section, to be compared with Figure 33-9, shows how, in atrioventricular septal defect with common atrioventricular junction (bracket), the junction is shared more or less equally between the four chambers, and there is a septal defect between the leading edge of the atrial septum and the crest of the ventricular septum (star). Note also, however, that the inferior leaflet of the common atrioventricular valve straddles the ventricular septum (arrows).

(Fig. 33-10), serves to emphasise the common nature of the junction. In all hearts having such an atrioventricular septal defect and common atrioventricular junction, the common atrioventricular valve of necessity both straddles and overrides. According to conventional wisdom,⁵ such hearts are not discussed under the heading of straddling and overriding. There is no morphological reason why they should not be thus described, since the feature of leaflets being tethered in both ventricles is found in both settings. Other hearts, nonetheless, can have a common atrioventricular junction guarded by a common atrioventricular valve, and not usually be described in terms of atrioventricular septal defects. These are the hearts with double inlet ventricle, but with both atrioventricular junctions guarded by a common atrioventricular valve. In these hearts (Fig. 33-11), the common atrioventricular valve does not straddle and override. In between these extremes, there are further spectrums of malformations that reflect the precise degree of override of the common valve. These series of anomalies parallel the spectrums of overriding of the right or left valves, to be described in the body of this chapter. In such hearts with eccentric commitment of the common atrioventricular valve, it is again hard to make the distinction between double inlet and biventricular atrioventricular connections. Here, the decision reached probably will affect clinical decision-making, since it will determine whether to proceed to univentricular as opposed to biventricular repair. From the morphological stance, the decision is also harder to make than when either the right or left valve is straddling, since it requires the use of a 75% rather than a 50% rule. In clinical terms, it is almost certainly the size of the ventricle which is most important in determining the feasibility of biventricular versus univentricular repair. The precise atrioventricular connection, however, is by no means insignificant. This is again made, therefore, on the basis of the perceived attachments of the overriding junction, using the best information available to reach this decision. We will not consider further in this chapter those hearts with common valve which are intermediate between the extremes of atrioventricular septal defect and double inlet

Figure 33-11 The four-chamber section of this heart shows that not all hearts with common atrioventricular junction and valve (*bracket*) have straddling of the leaflets. In this case, the common valve is exclusively connected to the right ventricle (RV) because of double inlet atrioventricular connection (compare with Fig. 33-10). LV, left ventricle.

ventricle, but they exist in the same patterns of right hand and left hand ventricular topology which will be discussed for straddling and overriding of those having separate right and left atrioventricular valves.

Before leaving the topic of definitions, we should address the problems of distinguishing a common valve from a straddling solitary valve associated with absence of one atrioventricular connection (see Fig. 33-9). We use the arrangement of the atrial septum as our arbiter. In almost all hearts in which one atrioventricular connection is absent, the atrial septum fuses with the parietal atrial wall so as to separate the blind-ending atrial chamber from the patent atrioventricular junction. This arrangement is seen even when the valve guarding the right or left atrioventricular junction is itself straddling and overriding between the ventricles (see Fig. 33-9). This morphological pattern serves to distinguish these hearts in which one atrium is connected to both ventricles, in other words, those with a uniatrial but biventricular atrioventricular connection, from other hearts with comparable connection of one atrium to both ventricles, so-called double outlet atrium, but in the setting of a common atrioventricular junction. In these latter hearts, which unequivocally have straddling and overriding of an atrioventricular valve, the valve itself is common to both the atriums because the atrial septum has failed to fuse with the parietal atrioventricular junction. The overall lesion, in the setting of common atrioventricular junction, is the consequence of malalignment between the atrial and ventricular septums, but with retention of the septal deficiency. This space, between the malaligned atrial septum

in these hearts and the atrioventricular junction, is the so-called ostium primum defect. It can be argued that, on morphogenetic terms, this interatrial communication can become gradually smaller until it disappears, and therefore that the entities should be grouped together. From the stance of strict morphology, nonetheless, the junction remains a common structure until the primary foramen, or the ostium primum, has closed. The hearts with common atrioventricular valves and double outlet atrium are discussed further in Chapter 27. Those with a uniatrial but biventricular atrioventricular connection⁶ will receive further attention in this chapter, and are also discussed in Chapter 31.

INCIDENCE AND AETIOLOGY

In that all atrioventricular septal defects with common orifice have a straddling valve as here defined, they should strictly be included in statistics concerning incidence. Because of problems of this kind, and because recognition of straddling and overriding is a recent event, it is difficult, if not impossible, to give precise figures. In our experience, straddling valves are recognised with more frequency now that they are specifically sought, particularly in anomalies such as congenitally corrected transposition (see Chapter 39), hearts with double inlet ventricle (see Chapter 31), and in double outlet right ventricle with subpulmonary ventricular septal defect (see Chapter 40 and Fig. 33-5). Clinical recognition of straddling, as opposed to overriding, of atrioventricular valves was not possible prior to the advent of cross sectional echocardiography. Until recently, straddling tended to be inferred when angiography demonstrated that the valvar orifice was overriding the ventricular septum. As overriding or straddling can exist in isolation, there were obvious diagnostic limitations. Straddling valves in the context of the congenitally malformed heart, therefore, should be considered relatively rare, but highly significant, malformations. In terms of aetiology, straddling mitral and tricuspid valves have been produced experimentally in rat fetuses exposed to teratogens,⁷ while straddling tricuspid valve was produced by preventing expansion of the right atrioventricular junction.⁸

MORPHOLOGY AND DIAGNOSIS

Although straddling right or left atrioventricular valves can be found with any segmental combination,^{1,6,9} description and diagnosis are simplified if they are considered in five series of malformations. In four of these series, either the right or left atrioventricular valve is straddling and overriding in the setting of right hand or left hand ventricular topology, respectively. As we have discussed, a common valve can also straddle and override with either right hand or left hand ventricular topology, and can show all the extremes between double inlet and biventricular atrioventricular connections. As explained, these variants with common valve will not be further discussed in this chapter, although it would be entirely appropriate to include such details. The fifth series is the uniatrial but biventricular atrioventricular connection.^{6,9} As we will see, there are also several morphological variants to be found within this prototype, depending on ventricular topology and the side of absence of the atrioventricular connection. First, we

Figure 33-12 The cartoon shows the extremes of the series of malformations, extending from concordant atrioventricular connections (A) to double inlet left ventricle (B), found when the right atrioventricular (AV) valve, morphologically tricuspid, straddles and overrides in the setting of right hand ventricular topology.

account for the four patterns in which either the right or left atrioventricular valve is straddling.

While it might appear self-evident that straddling of an atrioventricular valve implies the presence of a ventricular septal defect, hearts are found in which an overriding atrioventricular valve straddles the septum, but the valvar leaflets are firmly adherent to the septal crest as they straddle. In such cases, a bridging tongue between the straddling leaflets usually creates two orifices within the overriding valve, with one valvar orifice then opening into each ventricle. This situation is comparable to atrioventricular septal defect with common atrioventricular junction guarded by separate right and left atrioventricular valves (see Chapter 27).

Straddling Morphologically Tricuspid Valve in the Setting of Right Hand Ventricular Topology

As is shown in Figure 33-12, the extremes of this spectrum are concordant atrioventricular connections (see Fig. 33-12A) and double inlet left ventricle with right-sided incomplete right ventricle (see Fig. 33-12B). The essence of this series is that the valve usually overrides the postero-inferior part of a malaligned ventricular septum which does not extend to the crux (see Fig. 33-3). When the atrioventricular connections are concordant, the septum joins the atrioventricular junction in its postero-inferior quadrant, whereas when the connection is basically double inlet, the septum joins the junction more or less at the acute margin. When the degree of override is approximately equal, the septum joins the junction halfway between the crux and the acute margin (Fig. 33-13). Irrespective of the precise atrioventricular connection, the septum does not reach the crux, and is malaligned relative to the atrial septum. Because of this, there is an abnormal atrioventricular conduction system (Fig. 33-14). The atrioventricular node is formed at the site where the ventricular septum joins the atrioventricular junction, the bundle branches being disposed astride the postero-inferior part of the septum. We have, on one occasion, seen straddling of the tricuspid valve through

a muscular inlet defect, in the absence of override of the atrioventricular junction. In this setting, the atrioventricular connections were concordant, and the atrioventricular bundle arose from a regular atrioventricular node located in the atrial septum at the apex of the triangle of Koch.

The size and morphology of the right ventricle depend in part on the degree of override. When the valve is connected mostly to the right ventricle, the ventricle tends to be of more or less normal morphology. When the degree of override is such as to produce effective double inlet left ventricle, the morphology of the chamber can be virtually identical to the incomplete right ventricle typically seen in double inlet left ventricle. The ventriculo-arterial connections can be concordant or discordant. When the connections are concordant, the defect straddled by the valve has often been described as being of atrioventricular

Figure 33-13 Close-up of the right atrioventricular junction from a heart with straddling tricuspid valve (arrows) sectioned to replicate the four-chamber echocardiographic cut shows the essence of the malformation. The ventricular septum (star) is malaligned relative to the atrial septum, the latter structure supporting the leaflets of the atrioventricular valves at the same level. Because of the malalignment, the atrioventricular bundle (red line) takes origin from a node (cross-hatched oval) in the postero-inferior part of the atrioventricular junction.

Figure 33-14 The cartoon shows the course of the conduction system in a situation comparable to that shown in Figure 33-13, but as might be viewed by the surgeon in the operating room. The atrioventricular node is formed at the point of union between the malaligned ventricular septum and the right atrioventricular junction. A node is present at the apex of the triangle of Koch, but is unable to make contact with ventricular conduction tissues. (Modified from the original prepared by Gemma Price for *Surgical Anatomy of the Heart* and reproduced with her permission.)

canal type.^{10,11} This is an inappropriate description, since the essence of the atrioventricular canal malformation is a common atrioventricular junction. The straddling tricuspid valve arises from a separate right atrioventricular junction, and hence cannot be associated with an atrioventricular canal. Rarely, nonetheless, a common valve can override in a fashion analogous to the straddling tricuspid valve. This is when there is marked malalignment between the atrial and ventricular septal structures, and the common atrioventricular junction is connected predominantly within the dominant left ventricle. The atrioventricular conduction tissues are then disposed in similar anomalous fashion (see Fig. 27-24).¹² Double outlet right ventricle, and Fallot's tetralogy, can also be complicated by straddling of the tricuspid valve.

Straddling and overriding of the tricuspid valve are readily identified using cross sectional echocardiography (Fig. 33-15), and it is also usually possible to recognise the pathognomonic malalignment between the atrial and ventricular septal structures (Fig. 33-16). Such examinations show the precise morphology present, particularly when conducted via the transoesophageal portal. In the setting of straddling and overriding, the leaflets of both atrioventricular valves are attached to the atrial septum at the same level (see Fig. 33-16). In the rare instances of straddling without overriding, however, the integrity of the atrioventricular septum will produce normal off-setting of the leaflets of the atrioventricular valves (Fig. 33-17). The degree of overriding, and hence the precise atrioventricular connection, is determined by assessing the point of attachment of the malaligned ventricular septum to the right atrioventricular junction. This is best done in a cut in which the overriding junction and the ventricular septum are visualised without showing the orifice of the mitral valve. A normal four-chamber cut may be too anterior to detect

Figure 33-15 The cross sectional echocardiographic image, in four-chamber format, shows straddling of the leaflets of the tricuspid valve with effectively concordant atrioventricular connections. The overriding valvar orifice (bracket) is mostly supported by the morphologically (Morph) right ventricle (RV). LV, left ventricle.

Figure 33-16 This cross sectional echocardiographic image, again in four-chamber format, shows the pathognomonic feature for straddling tricuspid valve of malalignment between the atrial septum and the muscular ventricular septum. Note that the leaflets of the mitral and tricuspid valves are attached to the underside of the atrial septum at the same level.

the displacement of the postero-inferior extent of the ventricular septum. A straddling tricuspid valve should always be suspected when the right ventricle is found to be unexpectedly hypoplastic. This feature was of great value in the past, when angiography was the technique used for diagnosis (Fig. 33-18). The accuracy of echocardiographic diagnosis now obviates the need for angiography, particularly when accompanied by flow mapping, or when performed from the transoesophageal or transgastric windows.

Figure 33-17 This transthoracic subcostal echocardiogram shows straddling of the tension apparatus of the tricuspid valve (arrows) in the absence of junctional overriding. The atrioventricular septal structures were intact in this patient; note the normal wedged position of the aorta (AO). LA, left atrium; RA, right atrium; S, septum; V, left ventricle.

Straddling Morphologically Mitral Valve in the Setting of Left Hand Ventricular Topology

In the second series of malformations, the spectrum is between discordant atrioventricular connections (Fig. 33-19A) and double inlet right ventricle with right-sided incomplete left ventricle (see Fig. 33-19B). In this series, the right-sided morphologically mitral valve straddles the anterior part of a ventricular septum which does extend to the crux (Fig. 33-20).¹³ When the overriding atrioventricular junction is connected mostly to the left-sided morphologically right ventricle, then the atrioventricular connection is effectively double inlet right ventricle. The right-sided morphologically left ventricle may then be

Figure 33-18 The right ventricle is shown to be hypoplastic by angiocardiography in this patient with straddling tricuspid valve. The part of the right junction committed to the left ventricle is shown by unopacified blood. (Courtesy of the late Dr R. M. Freedom, Hospital for Sick Children, Toronto, Ontario, Canada.)

no more than a postero-inferior slit, particularly as the ventriculo-arterial connection is almost always double outlet from the dominant right ventricle. Double outlet right ventricle is also the expected ventriculo-arterial connection when the atrioventricular connections are discordant rather than double inlet (see Fig. 33-20). Alternatively, there may be single outlet with pulmonary atresia, the aorta arising from the right ventricle. Discordant

Figure 33-19 The cartoon shows the extremes of the series of malformations found when the right atrioventricular valve, in this instance morphologically mitral because of the presence of left hand ventricular topology, straddles and overrides. This combination produces discordant atrioventricular connections on the one hand (A), but double inlet right ventricle with right-sided incomplete left ventricle on the other hand (B). Compare with Figure 33-12. MLV, morphological left ventricle.

Figure 33-20 This heart has discordant atrioventricular connections and double outlet from the left-sided morphologically right ventricle (not seen in the photograph). The image shows straddling and overriding of the right-sided morphologically mitral valve (MV). Note that the septum extends to the crux (compare with Fig. 33-3). (Courtesy of Mr Don Perrin, Hospital for Sick Children, Toronto, Ontario, Canada.)

ventriculo-arterial connections are rare, and concordant connections even rarer. The disposition of the conduction tissues is dictated by the left hand pattern of ventricular topology.¹³ When the ventriculo-arterial connection is double outlet from the right ventricle, it is possible for both an anterior and a postero-inferior atrioventricular node to make contact with the ventricular conduction tissues, producing the so-called Monckeberg sling.^{14,15} This arrangement is in contrast to the expected situation in congenitally corrected transposition, where typically only the anterior node makes contact with the ventricular conduction tissues.¹⁶ A heart with congenitally corrected transposition and straddling mitral valve has been described, nonetheless, in which the only atrioventricular node was regularly positioned within the atrial septum.¹⁷ Both the presence of a sling, and the existence of a regular node, reflect the better alignment of the atrial and muscular ventricular septums in the presence of double outlet right ventricle.

The presence of straddling of the mitral valve should always be suspected when clinical investigation suggests discordant atrioventricular connections, but the morphologically left ventricle is small. Cross sectional echocardiography is again the diagnostic technique of choice (Fig. 33-21). Angiography in the past was able to show the division of the stream of blood leaving the right atrium, and it was thought that ventricular angiograms, taken in the appropriate projection, would illustrate the degree of override of the atrioventricular junction. All of these features are now better quantified using echocardiography, particularly with the increasing availability of the three-dimensional format. If necessary, tomographic techniques such as magnetic resonance imaging or computerised tomography will confirm the findings.

Figure 33-21 This cross sectional echocardiogram, taken subcostally, shows straddling of the tension apparatus of the morphologically mitral valve (MV) in a patient with left hand ventricular topology and effectively discordant atrioventricular connections. The pulmonary (Pulm.) trunk was arising, together with the aorta, from the morphologically right ventricle (Morph RV). Morph LV, right sided morphologically left ventricle.

Straddling Left-sided Morphologically Mitral Valve in the Setting of Right Hand Ventricular Topology

In this series of malformations, the extremes of the spectrum are concordant atrioventricular connections (Fig. 33-22A), and double inlet right ventricle with left-sided incomplete left ventricle (see Fig. 33-22B). This variant of straddling mitral valve,^{18,19} as with the lesion seen with effectively discordant atrioventricular connections, is again encountered most frequently in association with double outlet right ventricle, be the atrioventricular connections concordant or double inlet right ventricle. The essence of the anomaly is that the mitral valve straddles and overrides the antero-superior part of the muscular ventricular septum (see Fig. 33-4). With this arrangement, again as in the setting of discordant atrioventricular connections (see Fig. 33-20), the postero-inferior part of the septum does extend to the crux (Fig. 33-23). Because of this, the conduction tissues are located in their usual position for the normal heart irrespective of the atrioventricular connection.¹ The leaflet of the mitral valve which straddles into the right ventricle is itself frequently cleft.²⁰

Diagnosis of the anomaly using cross sectional techniques (Fig. 33-24), particularly combined with flow mapping and use of the transoesophageal window, is remarkably accurate. Though ventricular hypoplasia, when it occurs, usually affects the left-sided morphologically left ventricle, a small series of right-sided hearts have been described²¹ with usual arrangement and straddling mitral valve with concordant atrioventricular connections and double outlet right ventricle. In these patients, diagnosed using cross sectional echocardiography, it was the right

Figure 33-22 The cartoon shows the extremes of the series of malformations found when the left atrioventricular valve, in this instance morphologically mitral because of the presence of right hand ventricular topology, straddles and overrides. This combination produces concordant atrioventricular (AV) connections on the one hand (A), but double inlet right ventricle (RV) with left-sided incomplete left ventricle (LV) on the other hand (B). Compare with Figure 33-12.

Figure 33-23 The picture shows straddling of a left-sided morphologically mitral valve as seen from the left ventricular aspect in the setting of usual atrial arrangement and right hand-pattern ventricular topology. In this instance, the atrioventricular connections are concordant, and there is double outlet right ventricle. The other end of the spectrum is double inlet right ventricle. Note that the valve straddles the outlet part of a septum, which continues postero-inferiorly to reach to the crux.

ventricle which was hypoplastic. There was associated tricuspid stenosis and hypoplasia, a large right ventricular outflow tract, an antero-superior interventricular communication, and criss-cross atrioventricular relations. It proved possible to diagnose this pattern angiographically, either directly following left atrial injection, or by observing the flow of contrast-free blood through the annulus following a ventricular injection in the four-chamber projection.²⁰ As with the other entities discussed in this chapter, nonetheless, the need for angiographic investigation has now been obviated by the accuracy of cross sectional echocardiography.

Straddling Left-sided Morphologically Tricuspid Valve in the Setting of Left Hand Ventricular Topology

In the final series of malformations with biatrial connections, the spectrum extends from discordant atrioventricular connections (Fig. 33-25A) to double inlet left ventricle

Figure 33-24 This four-chamber echocardiographic cut, taken subcostally, shows straddling and overriding of the left-sided morphologically mitral valve in the setting of usual atrial arrangement, effectively concordant atrioventricular connections, and right hand ventricular topology. Both the pulmonary trunk and the aorta were originating from the morphologically right ventricle. Note that the straddling tension apparatus of the mitral valve produces marked subpulmonary obstruction.

with left-sided incomplete right ventricle (see Fig. 33-25B). The straddling valve overrides the postero-inferior part of the muscular ventricular septum, which does not extend to the crux (Fig. 33-26). The ventriculo-arterial connections in either type are usually discordant, but other connections must be anticipated. Whatever the atrioventricular connections, the ventricular conduction tissues arise from an anterolateral node in the right atrioventricular junction. A long non-branching bundle encircles the pulmonary valvar orifice to reach and branch on the antero-superior part of the muscular ventricular septum (Fig. 33-27).¹

As with all the other variants, the diagnosis is readily made nowadays using cross sectional echocardiography (Fig. 33-28). This shows both the degree of override of the valvar

Figure 33-25 The cartoon shows the extremes of the series of malformations found when the left atrioventricular valve, in this instance morphologically tricuspid because of the presence of left hand ventricular topology, straddles and overrides. This combination produces discordant atrioventricular connections on the one hand (A), but double inlet left ventricle (LV) with left-sided incomplete morphologically right ventricle (MRV) on the other hand (B). Compare with Figure 33-22.

annulus, and the precise attachments of the tension apparatus of the straddling valve.²² The entity should be suspected whenever the morphologically right ventricle is unexpectedly small in patients thought to have congenitally corrected transposition, or unusually large when the working diagnosis is double inlet left ventricle with left-sided incomplete right

ventricle. Angiography as a diagnostic tool has been rendered obsolete by the excellence of cross sectional echocardiography, particularly when interrogation is carried out from the transoesophageal portal. The diagnostic yield will improve still further as three-dimensional techniques become better established.

Figure 33-26 The image shows the morphologically left ventricle from a patient with congenitally corrected transposition and usual atrial arrangement. There is minimal overriding and straddling of the left-sided morphologically tricuspid valve (TV). Note that the ventricular septum does not extend to the crux.

Figure 33-27 The cartoon shows the disposition of the conduction tissues as would be seen through the right-sided morphologically left ventricle in a patient with congenitally corrected transposition and usual atrial arrangement with straddling of the left-sided morphologically tricuspid valve (left AV valve). Note that the bundle (dashed green line) runs cephalad to the ventricular septal defect (VSD) and the pulmonary (pulm.) valve. Compare with Figure 33-26.

Figure 33-28 This echocardiogram, taken in a patient with effectively discordant atrioventricular connections, shows the tension apparatus of the left-sided morphologically tricuspid valve (morph. TV) overriding the ventricular septum, which does not reach to the crux. The tension apparatus of the valve was also straddling. Morph LV, right-sided morphologically left ventricle; Morph RV, left-sided morphologically right ventricle.

Straddling Valves with Absent Atrioventricular Connection

The final group of hearts to be discussed in this chapter are those in which one atrioventricular connection is absent, but in which the solitary atrioventricular valve straddles and overrides the ventricular septum (see Fig. 33-9). Such hearts, which have a uniatrial but biventricular connection, are extremely rare and exceedingly complex anatomically.^{6,9} They are important for understanding the range of morphology to be found in congenitally malformed hearts, and they emphasise the value of sequential segmental analysis. Examples exist of absence of either the right or left atrioventricular connections, and of either right hand or left hand ventricular topology (Fig. 33-29). Furthermore, for each prototypic heart shown in Figure 33-29, there are two examples, depending on which ventricle is dominant. This means that there are at least eight possible arrangements, and most have now been well documented.^{6,9,22,23}

Ventricular topology has proved to be of great significance when categorising these hearts,^{6,9} the disposition of the conduction system in particular depending on this feature. Studies carried out in two patients revealed unexpected findings.⁹ In one, when the right atrioventricular connection was absent and the left valve was straddling in the setting of left hand ventricular topology, a sling of conduction tissue was encountered, with the posterior node formed in the left sided atrioventricular junction (Fig. 33-30). This finding points again to the crucial feature of the junction between the muscular ventricular septum and the atrioventricular junction in determining the location of the atrioventricular node, along with the equally important facet of ventricular topology. Also, irrespective of how the heart is imaged, the result will be heavily dependent on the ventricular topology, even in hearts in which the blood goes round the same way physiologically. And, from

Figure 33-29 The cartoon shows how, when there is absence of either the right or the left atrioventricular connection, the solitary atrioventricular (AV) valve, which will be right-sided (*left hand panels*) or left-sided (*right hand panels*), can straddle and override in patients with usual atrial arrangement when there is either right hand (*upper panels*) or left hand (*lower panels*) ventricular topology. Further variability is then seen in terms of the dominance of the ventricles, different ventriculo-arterial connection, and so on.

an embryological point of view, there is all the difference in the world between a heart with absent right connection in left hand and right hand topology, just as there is a great difference between straddling mitral and straddling tricuspid valve. It is usually, but not always, possible to predict the valvar morphology from the ventricular topology, and vice versa.⁹ Hence, it is best to establish both the morphology of the straddling valve and the ventricular topology. On occasion, nonetheless, in some hearts it may prove impossible to determine the topology of the ventricular mass.²⁴ Should that prove to be the case, clear and unambiguous description is essential.

In the hearts having a uniatrial but biventricular connection, the clinical picture will be dominated by the side of the absent connection, and by other associated anomalies, such as those that reduce the flow of blood to the lungs. The finding of unexpected ventricular morphology should alert to the possibility of the lesion, and echocardiography readily demonstrates the combination of a straddling valve with absence of one atrioventricular connection (Fig. 33-31). During echocardiographic examination, it is important to assess the competence of the straddling valve, since regurgitation is common, at least when it is the morphologically tricuspid valve which is straddling.²² Although, on some occasions, the ventricles are of comparable size, offering the theoretical option of surgical septation should the ventriculo-arterial connections be favourable, the morphology is so complex that the operative options are unlikely ever to extend beyond either palliation or construction of the Fontan circulation.

Figure 33-30 The cartoon shows the location of a sling of conduction tissue, viewed from the atrial aspect and shown relative to the ventricular mass in the main left hand and lower panel, in a heart with absent right atrioventricular connection (AVC) and straddling left atrioventricular valve (LAVV) as seen in the setting of left hand ventricular topology, shown in the upper right hand panel as seen in four-chamber projection from behind. There is a dominant left-sided right ventricle (RV) which gives rise to both arterial trunks, with the incomplete left ventricle (LV) in right-sided and inferior position. The compass in the upper left quadrant of the cartoon shows the orientation of the ventricular mass as seen in the lower part of the panel. Inf., inferior; Sup., superior.

Figure 33-31 This cross sectional echocardiogram, obtained from the subcostal window, shows absence of the right atrioventricular connection (Absent Rt AVC), with straddling and overriding of the solitary left atrioventricular (AV) valve into a ventricular mass with right hand topology. Note that the atrial septum fuses with the atrioventricular junction, meaning that the straddling valve is left-sided rather than common. Morph LV, morphologically left ventricle; Morph RV, morphologically right ventricle.

THERAPEUTIC OPTIONS

In determining the options for treatment, which will be surgical once the diagnosis has been made, it will be necessary to take note of the precise connections of the

overriding junction and the arrangement of the straddling tension apparatus, together with the morphology and size of the dominant and incomplete ventricles.²⁴ In the past, purely palliative options often offered the best chance of success, although increasing experience with conversion to the Fontan circulation (see Chapter 32) now suggests this will be the alternative should biven-tricular repair be deemed impossible. Palliative procedures may still be needed even if the decision is made to proceed eventually to conversion to the Fontan circulation. These have included redirection of the circulations at either atrial or arterial levels, banding of the pulmonary trunk or release of a previously placed band, and construction of systemic-to-pulmonary arterial shunts. In extreme cases, the regurgitant straddling valve has been replaced, with a conduit placed to the pulmonary trunk so as to bypass pulmonary stenosis.²⁵ Nowadays, construction of a bidirectional cavopulmonary connection is the most likely palliative option. Biven-tricular repair can be achieved in those with the most favourable anatomy. This is particularly the case when valvar overriding exists in the absence of straddling. This presents only a minor problem to the surgeon, since any patch placed to close a ventricular septal defect can be deviated to the plane which passes between the atrioventricular valves. By contrast, straddling of the valvar tension apparatus, occasionally with the apparatus from both valves straddling, presents major problems. In these instances, many will opt for functionally univentricular repair. If one atrioventricular connection is absent, then biven-tricular repair is virtually impossible, although it may theoretically be possible to resect the atrial septum and divide the overriding valve if each ventricle is of substantial size, and the ventriculo-arterial connections are appropriately arranged.

Should the decision be made to proceed with biven-tricular repair, then if the straddling tension apparatus inserts within 1 cm of the crest of the ventricular septum, the septal defect can be closed in such a way as to leave the cords initially on the wrong side of the ventricular septum on the correct side of the patch.²⁵ This is relatively straightforward if the cords are straddling towards the ventricle containing the greater part of the overriding valve, as would be the case in concordant atrioventricular connections with straddling mitral valve.²⁴ It is not so simple when the straddling cords insert on the far side of the ventricular septum from the surgeon, as is the case with straddling tricuspid valve and right hand ventricular topology. The technical challenge of securing the patch on the wrong side of the septum is then comparable with the technique used to avoid the conduction tissues in patients with discordant atrioventricular connections uncomplicated by straddling.²⁶ Sometimes it may be necessary to enlarge the defect so as to bring the straddling cords nearer its margin.^{25,27} Further possibilities include division of tendinous cords attached to a limited amount of atrioventricular valvar tissue. Alternatively, the cords may be passed through a slot in the patch.²⁸ The slot is then sutured to create the smallest possible residual defect consistent with free movement of the cord. When the straddling tension apparatus is attached only to one papillary muscle, or to an area of the muscular ventricular septum in the inappropriate ventricle, then

Figure 33-32 The cartoon shows the suggested morphogenetic sequences which link straddling of the right and left valves in the setting of right hand topology. The middle panel shows the normal heart. Straddling of the left-sided morphologically mitral valve produces a spectrum leading to double inlet right ventricle (RV) with left-sided and inferior incomplete left ventricle (LV), while straddling of the right-sided morphologically tricuspid valve produces a similar spectrum with double inlet left ventricle and right-sided incomplete right ventricle as the end point. The ventriculo-arterial connections will vary depending on the precise ventricular morphology. LAVV, left atrioventricular valve; RAVV, right atrioventricular valve.

that muscle may be sectioned at its base if it has no other cordal attachments. The septal defect can then be closed and the papillary muscle reattached to the patch or the intraventricular tunnel thus created.²⁹

There is also the problem of avoiding the conduction tissues when attempting to close the ventricular septal defect, or achieving septation, in hearts with straddling atrioventricular valves. As we have described, the arrangement is frequently abnormal, even in hearts with straddling tricuspid valve and concordant atrioventricular connections. Indeed, in many reported series, surgically induced atrioventricular dissociation has been a major complication.²⁸ In the past, this was presumably because the ventricular conduction tissues were presumed to arise from the regular atrioventricular node located in the triangle of Koch.³⁰ As we have emphasised, in this entity the node is formed at the point where the muscular ventricular septum makes contact with the atrioventricular junction. Success can be achieved in avoiding heart block, nonetheless, simply by the expedient of placing very fine sutures in the crest of the ventricular septum.²⁶ It would seem more prudent, nonetheless, for surgeons to attempt to avoid the known site of the atrioventricular node. This is always abnormal when the tricuspid valve straddles in the setting of right hand topology, in the group of hearts with straddling left valve in the setting of left hand ventricular topology, and usually deviates from the normal when the right valve straddles in this setting. These arrangements are already well recognised in patients with congenitally corrected transposition (see Chapter 39). All things considered, surgical repair of straddling valves is a daunting prospect. When straddling is minimal, and the patient is larger, closure of the defect by deviating the patch is to be recommended. This may also be done in infancy when there is no valvar regurgitation. Excellent results reported by some groups point to the potential advantages of this approach.^{26,29} When the morphology precludes deviation of the patch, it is still possible to replace the straddling valve and close the ventricular septal defect once the patients

have reached a suitable age. In these latter situations, nonetheless, many would consider construction of the Fontan circulation a safer approach, despite its long-term uncertainties (see Chapter 32).

MORPHOGENESIS

The various series of hearts with straddling valves are readily explained on the basis of abnormalities of connection of the developing atrioventricular junctions to the ventricles.³⁰⁻³³ During normal development with rightward ventricular looping (Fig. 33-32), the atrioventricular canal is initially committed exclusively to the developing left ventricle. With rightward expansion, and division, of the atrioventricular canal, the right atrium becomes connected to the developing right ventricle.³⁴ Incomplete connection of various degrees produces straddling of the right atrioventricular valve, while exaggerated commitment of the newly formed left atrioventricular junction to the developing right ventricle accounts for straddling and overriding of the left atrioventricular valve. The extreme of such exaggerated rightward commitment then explains pure double inlet right ventricle, the left ventricle remaining as the incomplete left-sided chamber. Exactly the same processes can occur with left hand ventricular looping, thus producing the other series of straddling valves (Fig. 33-33). Similar events, but with eccentric development of the atrial septum and fusion with the atrioventricular junction, will produce all the variants of straddling valve with absent atrioventricular connection. As we have discussed, straddling of an atrioventricular valve in the setting of absent atrioventricular connection produces one variant of double outlet atrium. The other variant is found in the setting of a common atrioventricular junction with gross malalignment of the atrial septum.³⁵ This is well explained on the basis of eccentric formation of the atrial septum, but retention of a common atrioventricular junction. As we have emphasised, it is the morphology of the atrial septum which serves to distinguish these lesions.

Figure 33-33 The cartoon shows the suggested morphogenetic sequences which link straddling of the right and left valves in the setting of left hand topology. The middle panel shows congenitally corrected transposition. Straddling of the left-sided morphologically tricuspid valve produces a spectrum leading to double inlet left ventricle (LV) with left-sided and superior incomplete right ventricle (RV), while straddling of the right-sided morphologically mitral valve produces a similar spectrum with double inlet right ventricle and right-sided and inferior incomplete left ventricle as the end point. As with the spectrums shown in Figure 33-32, the ventriculo-arterial connections will vary depending on the precise ventricular morphology. LAVV, left atrioventricular valve; RAVV, right atrioventricular valve.

These investigations, based on examination of autopsied specimens, discussed how the lesions were best explained on the basis of incomplete transfer of the atrioventricular canal to produce straddling tricuspid valve, or exaggerated displacement to produce straddling mitral valve. The findings from the developing heart over the past decade have shown the accuracy of the speculations.

Diseases of the Tricuspid Valve

PATRICK W. O'LEARY, JOSEPH A. DEARANI, and ROBERT H. ANDERSON

The most common congenital malformations afflicting the tricuspid valve are Ebstein's malformation and tricuspid valvar dysplasia. We will primarily consider Ebstein's malformation in this chapter. Isolated dysplasia of the tricuspid valvar leaflets, and other right ventricular abnormalities frequently mistaken for Ebstein's malformation, will be briefly described. Tricuspid valvar abnormalities or abnormalities of the morphologically right atrioventricular valve are also often associated with atrioventricular septal defects with common atrioventricular junction (Chapter 27), ventricular septal defect with straddling valve (Chapter 33), or pulmonary atresia with intact septum (Chapter 30). These lesions are described in detail in the appropriate chapters of our book.

NAMING OF THE TRICUSPID VALVAR APPARATUS

We have chosen to adopt an anatomically unambiguous system of names to describe the components of the tricuspid valvar apparatus. This will create some differences between the descriptions contained within this chapter and many previous publications. It seems best concretely to define this system to avoid potential confusion. The three valvar leaflets will be referred to as the anterosuperior, the septal, and the mural leaflets. The designation of the septal leaflet is already clear. The anterosuperior leaflet has most commonly been referred to as the anterior leaflet. The mural leaflet has often been called the posterior leaflet. This designation is anatomically incorrect. The mural leaflet is positioned inferiorly within the ventricular cavity, lying adjacent to the diaphragm in the normal heart. We recognise that abnormal valves often display rotation of their components away from the normal position. We prefer, therefore, to refer to this leaflet as mural, since it will invariably be more closely associated with the ventricular free wall than its counterparts.

EBSTEIN'S MALFORMATION

Ebstein's malformation has an extremely variable natural history depending on the degree of abnormality of the right ventricle and the tricuspid valvar apparatus, which may range from mild to severe. If the deformity of the tricuspid valve is severe, it may result in profound congestive heart failure in the neonatal period, or even in intra-uterine death. At the other end of the spectrum, patients with mild degrees of displacement and dysfunction may remain asymptomatic until late adult life or may remain symptomless throughout life.

Ebstein's own description¹ of the malformation in 1866, with illustrations by Dr Weiss (Fig. 34-1), was based

upon the anatomical findings relating to the heart of Joseph Prescher, a 19-year-old labourer with cyanosis, who had been troubled with dyspnoea and palpitations since childhood. The premortem diagnosis had been congenital cardiac defect. The first case described in the English literature was not published until 1900.² It was not until 1951 that the diagnosis was made during life, using angiocardiology.³ In the 1950s, successful surgical palliation was achieved, and the association with Wolff-Parkinson-White syndrome had been recognised. In the 1960s came the first attempts at corrective surgery, including valvar replacement⁴ and repair.⁵ The malformation accounts for no more than 0.3% to 0.5% of congenital heart disease.^{6,7} Equal numbers of male and female patients with Ebstein's malformation are usually observed.^{8,9}

With the advent of cross sectional echocardiography,¹⁰ it became much easier to make the diagnosis, even in fetal life.⁸ The malformation is now known to be more common

Figure 34-1 The illustration of the heart of Joseph Prescher as seen from the ventricular aspect, and as illustrated for Wilhelm Ebstein by Dr Weiss. Note how the leaflets of the deformed valve close in bifoliate fashion, forming a keyhole orifice that opens towards the outlet component of the right ventricle.

than previously appreciated, and there has been a marked change in the spectrum of disease seen by paediatric cardiologists. In the era of echocardiographic diagnosis, review of a series of over 200 cases collected from hospitals in south-east England revealed an appreciable increase in the number of diagnosed cases, with more than half of the patients aged less than 1 year at diagnosis.⁹ Surgical correction, with repair or replacement of the malformed valve and closure of the atrial septal defect, is known to produce excellent results.^{11–17} Conversion to the Fontan circulation or cardiac transplantation are reserved for extreme situations.^{11,12}

We will limit our discussions in this chapter to Ebstein's malformation as found in hearts with concordant atrioventricular connections, with or without associated defects. The lesion, of course, is well recognised as being part of the substrate of congenitally corrected transposition, when it typically afflicts the left-sided morphologically tricuspid valve subserving a systemic function. This combination is considered in Chapter 39.

Definition and Anatomy

Ebstein's malformation is often thought of as a primary disorder of the tricuspid valve. In reality, it is a manifestation of a more global aberration in myocardial development. Those afflicted with Ebstein's malformation invariably display abnormalities in both myocardial structure and function, as well as the characteristic valvar deformities. The right ventricle and tricuspid valve are universally involved, while changes in the left heart are less common.¹³

The hallmark of Ebstein's malformation is displacement of the points of attachment, or the hinges, of the septal and mural leaflets into the right ventricle, away from the atrioventricular junction. This results from failure of these leaflets fully to separate from the ventricular wall during cardiac development. The anterosuperior leaflet, in contrast, has a different developmental origin.¹⁴ Because of this, its junctional hinge usually retains a normal position. It had already been recognised late in the 19th century that formation of the valvar leaflets was a relatively late embryologic event.¹⁵ At the time of closure of the embryonic inter-ventricular communication, the septal and mural leaflets of the tricuspid valve have not begun to develop. These are

produced subsequently by delamination of the superficial layer of the ventricular myocardium.^{14,16}

In hearts with Ebstein's malformation, this failure to delaminate results in the tricuspid valvar leaflets remaining variably adherent to the underlying right ventricular and septal myocardium. Such failure to delaminate creates the characteristic displacement of the annular attachments of the valve and its functional orifice. This displacement is not linear, but spiral in nature. The effect is to move the tricuspid apparatus both anteriorly and towards the right ventricular apex (Fig. 34-2). The valvar hinge points are shifted into the body of the ventricle, and the functional orifice of the tricuspid valve moves to the junction between the inlet and the remaining apical trabecular and outlet components of the right ventricle, shown as the dotted line in Figure 34-2A. In the most severe cases, the functional leaflets may be positioned within the outlet itself. The adherent portions of the valvar leaflets usually have little or no motion. This typically leads to tricuspid regurgitation, or more rarely to stenosis.

In hearts studied in the autopsy room, mild cases can be encountered in which only the hinge of the septal leaflet is displaced away from the atrioventricular junction. Such cases are found most frequently in the setting of pulmonary atresia with an intact ventricular septum (Fig. 34-3). Cases with pulmonary atresia and an intact ventricular septum, of course, are not diagnosed primarily as Ebstein's malformation. It is certainly unusual to find such mild examples at autopsy in patients diagnosed clinically with Ebstein's malformation.¹⁷ In the absence of pulmonary atresia, it is unlikely that such minimal changes would produce the typical, if indeed any, symptomatology.

Problems also exist during life in distinguishing such minimal displacement of the septal leaflet from the typical valvar off-setting found in the normal heart (Fig. 34-4). In those cases coming to clinical attention, the entirety of the tricuspid valvar apparatus is malformed, and obviously so. In almost all cases, nonetheless, it is only the septal and mural leaflets that have their annular attachment displaced from the atrioventricular junction, with sparing of the proximal attachment of the anterosuperior leaflet.^{17–19}

A major problem for the morphologist in analysing these cases coming to clinical attention is precisely to

Figure 34-2 The cartoons show the rotational shift of the functional tricuspid orifice from the atrioventricular junction to the plane that divides the trabecular and outlet zones of the ventricle (*heavy dashed line in A*). The observed planes of the effective valvar orifices of the hearts with Ebstein's malformation studied by Schreiber and colleagues are shown by the ovals in **B**.¹⁷ The effective displacement of the functional tricuspid valve (*heavy dashed line*) away from the atrioventricular junction (*dotted line*) is rotational, not linear. This rotation is spiral in nature and is directed both towards the apex and, more important, anteriorly towards the outflow tract.

Figure 34-3 This heart has pulmonary atresia with intact ventricular septum. Note the mural hypertrophy that has obliterated the apical trabecular component and severely narrowed the outflow component leading to the imperforate pulmonary valve. The hinge of the septal leaflet of the tricuspid valve is deviated away from the atrioventricular junction (yellow dotted line), but the inferior mural leaflet has a normal annular attachment.

Figure 34-5 This view showing the atrial aspect of the deformed valve illustrates how the anterosuperior leaflet retains its normal attachment at the atrioventricular junction (red dotted line), but the septal and mural leaflets have their hinge points attached well away from the atrioventricular junction (compare red dashed and green dotted lines). Note that the leaflets of the deformed valve will close in bifoliate fashion. Note also the thinned wall of the atrialised inlet ventricular component.

Figure 34-4 These two echocardiographic images show tomograms taken in an apical four-chamber plane of a normal heart on the left and a heart afflicted with Ebstein's malformation on the right. The hinge point of the normal septal tricuspid leaflet is positioned slightly towards the cardiac apex relative to the septal hinge point of the anterior mitral leaflet (outlined by the arrows in the left hand panel). This displacement is exaggerated in hearts with Ebstein's malformation, as shown in the image to the right. This can be quantitated by the displacement index, dividing the distance between the valvar insertions divided by the body surface area. A value of greater than 8 mm/m² is diagnostic of Ebstein's malformation. It should be noted that the valvar leaflets are also abnormal in Ebstein's malformation. In the case illustrated here, the leaflets are thickened and moderately dysplastic. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

distinguish, in the abnormal valve, the boundaries between the mural and anterosuperior leaflets. In fact, the essence of the malformation is that the leaflets adopt a bifoliate configuration, with a plane of closure at the junction of the inlet and the remaining components of the right ventricle (Figs. 34-5 and 34-6).

It is the appreciation of this abnormal position and structure of the valve that is the key to subsequent analysis and, arguably, to selection of appropriate treatment.

The abnormal, displaced location of the valve represents a rotational or spiral deformity (Figs. 34-2 and 34-7) rather than a linear, downward or apical, displacement that has received attention in the past.

There is, nonetheless, marked variation from patient to patient. The variability reflects the degree of formation of the septal leaflet, the nature of the distal attachments of the anterosuperior and mural leaflets, and the amount of mobility/tethering of the anterosuperior leaflet. In the typical diseased valve as seen in the postmortem room, the septal leaflet is either represented by an array of verrucous remnants adherent to the septum towards the ventricular apex (see Fig. 34-5), part of a tongue that becomes continuous with the anterosuperior leaflet, or a circular remnant on the septum (Fig. 34-8). It was the latter arrangement that was seen in the initial heart described by Ebstein.¹ In either event, the septal leaflet may seem to be absent when attention is directed to the ventricular inlet component (Fig. 34-9). It is when assessment is redirected at the junction between the inlet component and the functional right ventricle that the valvar leaflets are seen, forming a bifoliate valvar mechanism (Fig. 34-10).

The functional part of the ventricle, therefore, is made up of the apical trabecular and outlet components beyond the plane of coaptation of the leaflets. As already indicated,

Figure 34-6 This view of the ventricular aspect of the deformed valve, from a different heart than that shown in Figure 34-5, shows the bifoliate pattern of closure between the anterosuperior leaflet and the deviated septal leaflet (*red dotted line*). The abnormal valve opens towards the outlet of the functional right ventricle, made up of the outlet and apical ventricular components. Compare this heart with the original specimen described by Ebstein himself (Fig. 34-1).

Figure 34-7 This view of the atrial aspect of a typically deformed valve shows the rotational displacement of the hinges of the septal and mural leaflets (*dashed line*) away from the atrioventricular junction (*dotted line*). Note the connecting tongue with the anterosuperior leaflet, the latter retaining its normal attachment at the atrioventricular junction. The resulting valvar orifice points towards the right ventricular infundibulum.

the mural and anterosuperior leaflets themselves tend to be combined as an abnormal curtain, which forms the parietal part of the abnormal bifoliate valve (see Fig. 34-5). The part formed by the anterosuperior leaflet usually retains its normal hinge from the atrioventricular junction along the

Figure 34-8 In this specimen, the septal leaflet is represented by a circular remnant, as in the initial case described by Ebstein. Note the focal attachments distally of the anterosuperior leaflet.

Figure 34-9 This specimen was prepared by making a simulated four-chamber section, having repaired a cut initially made into the wall of the inlet component. The section shows that the atrioventricular junction, as seen in this section, is essentially unguarded, the valvar leaflets being rotated towards the ventricular apex (see Fig. 34-10).

supraventricular crest, but the hinges of the valve move increasingly away from the junction as attention is directed to the attachments along the diaphragmatic surface of the ventricular mass. When seen in the postmortem room, this arrangement can give the impression of forming a potentially competent valve. In other cases, nonetheless, the valvar mechanism is clearly seen to be incompetent, due to either inadequate leaflet size, mobility, or fenestrations in the body of the leaflet itself (Fig. 34-11). Relative to the

Figure 34-10 This image shows the anterior part of the four-chamber section also illustrated in Figure 34-9 but now photographed from the posterior aspect. It shows how the valvar leaflets guard the junction between the atrialised inlet and the functional right ventricle, forming a bifoliate valvar mechanism (dotted line).

Figure 34-11 This image shows the lateral and anterior portions of the right atrium and ventricle. The anatomic atrioventricular junction is marked by the dotted line. There are multiple points of tethering and failed delamination. In addition, there are two large fenestrations (arrows) in the sail-like anterosuperior leaflet of the tricuspid valve. In cases like this, tricuspid regurgitation originates not only from the functional orifice of the displaced valve, out of the plane of this image, but also from these fenestrations, complicating attempts at surgical repair. RA, right atrium; RV, right ventricle; RVOT, right ventricle outflow tract.

mass of the atrialised right ventricle, the functional valvar orifice is frequently judged to be stenotic. In this setting, the upstream components of the right side of the heart, both the atrium and the right ventricular inlet, are dilated and thin walled. This produces anatomic atrialisation.

Further variation is then seen in the nature of the distal attachments of the mural and anterosuperior components of the valvar curtain, which are almost always additionally dysplastic.²⁰ In some cases, the anterosuperior leaflet retains its focal attachment to the medial and anterior papillary muscles (see Fig. 34-8). In the most florid cases, the entire leading edge of the anterosuperior leaflet is attached

Figure 34-12 In this heart, the anterosuperior leaflet and the connecting tongue with the septal leaflet have a linear attachment at the ventricular apex. Note the additional tethering of the ventricular aspect of the leaflet and the keyhole orifice pointing towards the ventricular outlet.

linearly to a muscular shelf formed between the inlet and apical trabecular components of the ventricle (Fig. 34-12). Between these extremes are found hearts in which the edge of the leaflet is attached in hyphenated fashion along the muscular shelf (Fig. 34-13). Further abnormal tetherings can be found between the ventricular aspect of the abnormal leaflets and the parietal ventricular wall (Fig. 34-14). Such tetherings serve to constrain still further the motion of the abnormal sail produced by the combined mural and anterosuperior leaflets.^{21,22} When the valvar mechanism is arranged as a bifoliate structure, then its opening is adjacent to the septum and is directed towards the ventricular outlet component. This keyhole can become increasingly restricted and stenotic. Should the leaflets fuse along the edges of the keyhole, the result is tricuspid atresia in the setting of Ebstein's malformation (Fig. 34-15).

The essence of symptomatic Ebstein's malformation, therefore, is formation of an abnormal bifoliate valvar mechanism, with septal and parietal components, at the junction between the atrialised inlet part of the right ventricle and the functional right ventricle, the latter comprising the apical and outlet components. Although the annular attachments of the septal leaflet of the valve are displaced from the atrioventricular junction, the triangle of Koch continues to be the landmark for the atrial components of the atrioventricular conduction tissue axis. Right bundle branch block is commonly found and may be caused by fibrosis in the distal conduction tissue. The frequent presence of accessory muscular pathways across the atrioventricular junctions results in a high incidence of preexcitation, this feature being found in up to one quarter

Figure 34-13 In this heart, the connecting tongue has hyphenated attachments at the ventricular apex, again with additional tethering to the parietal ventricular wall.

Figure 34-15 In this specimen, the keyhole orifice is blocked by fusion of the valvar leaflets, producing tricuspid atresia in the setting of Ebstein's malformation.

of patients.⁷ The accessory pathways are often multiple and are usually found to the right of the inferior paraseptal space or in the parietal part of the junction.²³ When found laterally, they frequently arise from a remnant of atrioventricular ring tissue and produce the so-called Mahaim variant of pre-excitation.²⁴

As we have already discussed, the abnormally located line of attachment of the valvar leaflets divides the right

ventricle into proximal atrialised and distal functional portions. The proximal portion lies between the atrioventricular junction and the displaced attachments of the leaflets. This atrialised portion has walls of ventricular myocardium but in severely affected patients tends to be smooth, thin-walled, and dilated, with a high content of fibrous tissue. When very thin, it moves paradoxically during ventricular systole, and it may also expand during atrial systole. Its electrical potentials are ventricular, but its pressure pulse shows an atrial waveform.

The cavitory portion of the functional right ventricle is usually smaller than the normal ventricle. This feature, however, may be modified by dilation, which is a frequent finding. The functional portion consists of the infundibulum, the apical trabecular component, and that portion of the ventricle beneath the distal attachments of the combined mural and anterosuperior leaflets. The walls of this functional ventricle, particularly when dilated, are also usually thinner than normal. They contain fewer than normal myocytes and more fibrous tissue.²⁵ Left ventricular abnormalities are frequent. They can sometimes simply be the consequence of the gross dilation of the right-sided chambers. In severe cases, the left ventricular free wall also has an abnormally high content of fibrous tissue, although its thickness is usually normal.²⁵ The mitral valve is frequently nodular and thickened, and prolapse of the leaflets is common.

Associated cardiac defects are also common, particularly in the patients diagnosed in fetal or neonatal life. Almost all patients have a co-existing interatrial communication at the oval fossa, usually a patent foramen. Any type of communication, nonetheless, may be present, including

Figure 34-14 The anatomic specimen on the left and the echocardiographic four-chamber image to the right, demonstrate extremely severe examples of Ebstein's malformation. No remnants of the septal leaflet are present within the inlet. Even the anterosuperior leaflets have failed to fully delaminate in these hearts, being firmly adherent to the underlying right ventricular myocardium (arrows). The anterosuperior leaflet in the echocardiographic example has a small segment that retains its junctional hinge (black asterisk). The anatomic specimen displays the rare situation in which even the hinge of anterosuperior leaflet is displaced into the ventricular cavity (anterior to the plane shown in this photograph). The anatomic atrioventricular junction is outlined by the white asterisks in the anatomic specimen. aRV, anterior right ventricle; LA, left atrium; LV, left ventricle; RA, right atrium.

atrioventricular septal defects in the setting of a common atrioventricular junction. A large spectrum of other lesions has been described in addition to atrioventricular septal defects, including ventricular septal defects, tetralogy of Fallot, aortic coarctation, and persistent patency of the arterial duct. The most common associated defect is pulmonary stenosis or atresia, which is found in up to one third of those presenting in infancy.²⁶ Obstruction of the right ventricular outflow tract is commonly associated with Ebstein's malformation when diagnosed in fetal life.⁸ In this setting, it may be difficult to distinguish structural from functional pulmonary atresia using echocardiography, especially in the presence of severe tricuspid regurgitation. In either case, the pulmonary valvar abnormality is probably secondary to the malformation of the tricuspid valve, with hypoplasia of the outflow tract resulting from low anterograde flow through the right heart. When severe Ebstein's malformation is associated with fetal and neonatal distress or death, both lungs are usually hypoplastic but otherwise normal. The hypoplasia is secondary to the gross cardiomegaly, itself caused by dilation of the right heart.²⁷

In the setting of gross dilation of the heart because of severe tricuspid valvar incompetence, whether the consequence of Ebstein's malformation or dysplasia of the valvar leaflets, the overall ventricular myocardium can become particularly thin. This should not be described as Uhl's malformation. In the lesion described by Uhl,²⁸ the tricuspid and pulmonary valves were both normal. The essence of Uhl's malformation is congenital absence of the parietal myocardium, histological analysis showing that the epicardial and endocardial layers of the wall lie edge-to-edge.²⁹ It is also a mistake to correlate fibro-fatty replacement of the right ventricular parietal walls with either Ebstein's malformation or Uhl's malformation. Fibro-fatty replacement is the essence of arrhythmogenic right ventricular cardiomyopathy, now recognised as a cardiomyopathy in its own right, with various genetic causes (see Chapter 54). While dysplasia of the valvar leaflets is often an integral part of Ebstein's malformation, dysplastic leaflets can also be found when retaining their normal hinges at the atrioventricular junction (Fig. 34-16). Such dysplasia of normally hinged leaflets can produce just as much valvar incompetence as Ebstein's malformation. Isolated dysplasia can produce the same wall-to-wall heart,³⁰ with the same consequences for pulmonary problems in the neonatal period.²⁷

Causation and Genetics

No specific cause has been consistently associated with Ebstein's malformation. Based on retrospective case reporting, treatment with lithium during the first trimester of pregnancy was thought to be strongly associated, producing a 400 fold relative risk, with the occurrence of Ebstein's malformation in the fetus.³¹ More recent cohort and case-control epidemiologic studies have not confirmed these initial findings.³² In contrast, these more rigorous studies found that, while the frequency of all congenital malformations was increased with gestational exposure to lithium, the relative risk for any malformation, not only cardiac, was only two to three times that of non-treated mothers. More importantly, although the frequency of all congenital cardiac malformations was greater in pregnancies exposed to lithium, there was no increase in the frequency

Figure 34-16 This specimen has unequivocal dysplasia of the leaflets of the tricuspid valve but does not exhibit Ebstein's malformation, the leaflets retaining their normal hinges from the atrioventricular junction.

of Ebstein's malformation relative to controls. Given the rarity of Ebstein's malformation, these studies did not have the power completely to exclude a connection between lithium and the development of Ebstein's malformation. They do conclusively demonstrate that the relative risk of treatment with lithium during pregnancy is much less than was originally estimated from the retrospective case reports. The decision to continue or discontinue such treatment during pregnancy must now be made by weighing the relative risk of teratogenicity against the risks of relapse of manic/depressive disease in the mother.³² The majority of cases of Ebstein's malformation are sporadic, but some familial cases have been reported. There continues to be a difference of opinion as to whether there is a major hereditary basis for transgenerational transmission in Ebstein's malformation.^{33,34}

PATHOPHYSIOLOGY AND CLINICAL ASPECTS OF EBSTEIN'S MALFORMATION

The broad range of anatomic severity seen in Ebstein's malformation, combined with the variable myopathy, produce a wide spectrum of clinical and haemodynamic manifestations. The pathophysiologic changes are related to several factors. These include the functional state of the tricuspid valve in terms of the degree of regurgitation or more rarely, stenosis, the presence, or absence, and size of the interatrial communication or other congenital cardiovascular malformations, the degree of right ventricular dysfunction, and the amount of left ventricular dysfunction. To a lesser degree, the pathologic substrates predisposing to tachyarrhythmias produce an additional dimension contributing to the pathophysiology.

The dysfunctional nature of the right ventricular myocardium, and the co-existing abnormalities of the tricuspid valve, impair flow through the right heart and the pulmonary circulation. The interaction between the dilated right atrium and the atrialised segment of the right ventricle are perhaps just as important in the creation of ineffective patterns of flow within the right heart. During ventricular systole, the atrialised right ventricular myocardium is

contracting. There is no valvar tissue separating this area from the true atrial chamber and the great veins. This results in increased venous pressure, and effectively increases resistance to forward flow. This decreases the ability of the great veins to empty into the anatomic right atrium while its myocytes are relaxed. The increase in resistance to flow out of the atrium will also augment the amount of right-to-left shunting through any co-existing interatrial communication.

When the atrialised portion of the right ventricle relaxes, it will expand, and can even balloon outwards during true atrial contraction. This creates a reservoir for venous blood, and decreases the amount of effective forward flow that crosses the abnormal tricuspid valve. This to and fro flow pattern between the right atrium and the atrialised right ventricle not only decreases effective output from the right heart, but also provides an ongoing stimulus for atrial dilation and atrial arrhythmias, even when there is little transvalvar regurgitation. The degree of functional impairment experienced by patients with Ebstein's malformation has been directly related to these anatomic and physiologic abnormalities. Shiina and colleagues¹⁰ found that a small functional right ventricle and large atrialised right ventricle, extreme displacement or absence of the septal leaflet, the degree of displacement or tethering of the anterosuperior leaflet, and the aneurysmal dilation of the right ventricular outflow tract were all associated with reduced functional state as measured using the categorisation prepared by the New York Heart Association.

Although the primary focus in patients with Ebstein's malformation has been on right-sided structures, there have been an increasing number of reports of left-sided abnormalities, specifically in left ventricular size, shape, and function.³⁵⁻³⁷ In the past, these have been attributed to the degree of enlargement of the right heart compromising the left ventricle, and to leftward diastolic bowing of the interventricular septum. Radionuclide scans and cineangiograms have shown impaired left ventricular function at rest in unoperated patients. During formal exercise testing, most unoperated patients show an appropriate increase in left ventricular ejection fraction due to a reduced end-systolic volume and unchanged end-diastolic volume.³⁷ Recently, however, Attenhofer and colleagues^{13,38} reported that one-fifth of their cohort of patients with Ebstein's malformation had a markedly abnormal echocardiographic appearance of the left ventricular myocardium. These patients displayed segments of left ventricular myocardium with multiple layers and deep intratrabecular recesses, consistent with myocardial noncompaction. An additional one-tenth had hypertrabeculated segments of left ventricular myocardium reminiscent, but not diagnostic, of noncompacted myocardium. Although most patients had satisfactory left ventricular function, a small percentage showed severe systolic and diastolic dysfunction, even contributing to the need for transplantation in one young patient.³⁸ These left-sided myocardial abnormalities, although seen in only a fraction of patients, support the concept that Ebstein malformation is actually a global myocardial disorder that primarily manifests itself within the right ventricle and its derivative, the tricuspid valve.

The infant with Ebstein's malformation poses an especially difficult clinical problem. Pulmonary vascular resistance is always high immediately after birth, and usually

decreases fairly rapidly in the first days of life. The infant with severe Ebstein's malformation is poorly prepared to deal with the transition to the neonatal circulation. The combination of right ventricular myopathy, tricuspid regurgitation, and elevated pulmonary resistance can lead to poor pulmonary perfusion when the arterial duct constricts or closes. Venous pressures rise, leading to right-heart failure and cyanosis due to right-to-left shunting across the oval foramen. Until the pulmonary resistance decreases, and the pulmonary flow increases, these infants present a diagnostic and therapeutic dilemma. Patency of the pulmonary outflow tract and valve must be confirmed. This can be done by demonstrating opening of the pulmonary valvar leaflets by cross sectional echocardiographic scans, or by documenting either forward, or more commonly regurgitant, flow across the valve using Doppler techniques.

In the rare case where echocardiographic findings are inconclusive, an angiogram demonstrating pulmonary regurgitation following injection of contrast into the arterial duct, or the ability to advance a catheter across the valvar orifice, are other methods that can confirm patency of the right ventricular outflow tract. When the outflow tract is open, infusions of prostaglandin to maintain ductal patency, with or without mechanical ventilation, will often allow the baby to transition to the postnatal circulation without the need for palliative surgery.

Clinical Presentation

Patients with Ebstein's malformation may present at any age. The most severe cases present prenatally, or as newborns. Prenatal diagnosis is dependent upon ultrasonic screening examinations. Fetal presentation is accompanied by increased heart size, a significant incidence of fetal hydrops and, in the most severe cases, pulmonary parenchymal hypoplasia secondary to marked cardiac enlargement. Prenatal arrhythmia is not common. Newborns most often present with cyanosis, while slightly older infants present with a combination of desaturation and symptoms of cardiac failure. Murmurs and arrhythmias are more frequently encountered as presenting complaints in older patients. Although some patients remain asymptomatic, most will have some cardiovascular symptoms. Beyond infancy, the majority will display abnormal fatigueability, dyspnoea, or cyanosis with exertion or palpitations. Palpitations in a cyanotic child should raise the possibility of Ebstein's malformation (Table 34-1).^{9,39,40}

Ultrasonic technology has significantly influenced the age at which most patients with Ebstein's malformation are diagnosed. In 1979, Guiliani and colleagues found that just under one-third of patients were diagnosed before 4 years of age. Another two-fifths were diagnosed before the age of 19, with the remainder presenting in adulthood, some at 80 years of age.^{40,41} In contrast, in the experience reported by Celermajer and colleagues in 1994⁹ (see Table 34-1), three-fifths came to clinical attention before the age of 1 year, with half diagnosed prenatally or as newborns. One-tenth presented between 1 and 12 months of age, with only three-tenths presenting as children or adolescents. Despite the increased availability of ultrasonic examination

TABLE 34-1

MAJOR FEATURES OF EBSTEIN'S MALFORMATION IN 220 SUBJECTS AT PRESENTATION

	Prenatal (N = 21)	Neonate (N = 88)	Infant (N = 23)	Child (N = 50)	Adolescent (N = 15)	Adult (N = 23)	All (%)
Cyanosis	0	65	8	7	2	1	83 (38)
Heart failure	0	9	10	4	2	6	31 (14)
Murmur	0	8	3	33	5	3	52 (24)
Arrhythmia	1	5	1	6	6	10	29 (13)
Abnormal prenatal ultrasound	18	0	0	0	0	0	18 (8)

Neonate = 0–1 month; infant = 1 month–2 years; child = 2–10 years; adolescent = 10–18 years; adult = >18 years.

in this more recent cohort, one-tenth remained undiagnosed until adulthood.⁹

Physical Findings

Growth and development are generally normal. Inspection reveals cyanosis and digital clubbing in patients with an associated right-to-left shunt. Many have an unusual facial coloration, described as violaceous hue, flushed, florid, red-cheeked, or malar flush.⁴⁰ Usually these patients have an associated mild polycythemia. Prominence or asymmetry of the chest is a frequent finding secondary to the dilated nature of the right heart. Arterial and venous pulsations are usually normal, even in the presence of tricuspid insufficiency. The jugular venous pulsations may not have a large V wave because of poor transmission of the venous pulse wave in the presence of a dilated and compliant right atrium. The praecordium is usually not overactive.

After the neonatal period, it is auscultation that often alerts the physician to the diagnosis of Ebstein's malformation. Many patients have multiple sounds and murmurs present, especially those with mobile anterosuperior valvar leaflets. These multiple sounds are so characteristic as to stand out even to the untrained ear. Occasionally, the heart sounds are soft, but usually they are of normal intensity. The first heart sound is widely split because of increased excursion of the anterosuperior leaflet and the subsequent delayed closure of the abnormal tricuspid valve. The second heart sound is also widely and persistently split owing to late closure of the pulmonary valve, believed to be due to right bundle branch block. Ventricular filling sounds

are common contributors to the multiplicity of heart sounds. In the presence of so many heart sounds, there is frequently a gallop or quadruple rhythm, or cadence quality, which is fairly easily recognised. A holosystolic murmur, typically graded at 2 to 4 out of 6, is found along the left sternal border in those with an organised jet of tricuspid regurgitation. Low-intensity diastolic murmurs can be appreciated in the same location as a result of antero-grade flow across the tricuspid valve. All murmurs tend to vary with respiration, increasing during inspiration. There may be few murmurs present in patients with very little functional tricuspid valvar tissue, since the flows between right atrium and the ventricle are essentially unrestricted and not turbulent. The first heart sound is single in these cases.

Electrocardiography

The electrocardiogram is usually abnormal and helps to confirm the clinical diagnosis⁴⁰ (Fig. 34-17). Although sinus rhythm is usually present at the time of initial diagnosis, atrioventricular dissociation or atrial fibrillation can be found in a few patients. In large series, one-third to one-half of the patients have prolonged PR intervals, and one-fourth to three-fourths meet the criteria for right atrial enlargement, showing so-called Himalayan P waves.⁴⁰ The QRS axis in the frontal plane occasionally shows right-axis deviation. Most patients have right bundle branch block, and many have low-voltage QRS complexes in the right praecordial leads. Findings consistent with right ventricular hypertrophy are extremely uncommon.

Figure 34-17 This electrocardiogram comes from an infant with Ebstein's malformation. The QRS axis is shifted to the right (175 degrees), and there is evidence of prominent atrial enlargement with large P waves that exceed the voltage achieved by the ventricular QRS complex in some leads (P waves in leads aVR, aVL, and V1 are indicated by the series of three arrows). The rhythm is slightly irregular due to occasional premature contractions.

Up to one-quarter of patients with Ebstein's malformation have the Wolff-Parkinson-White pattern on their electrocardiogram.^{40,42} This is due to the presence of accessory myocardial atrioventricular connections across the insulating plane of the atrioventricular junction. Several resting or exercise electrocardiograms or 24-hour ambulatory electrocardiograms may have to be examined to find the characteristic pattern. Occasionally, the pattern is transient or intermittent.⁴³⁻⁴⁵ In addition, concealed accessory pathways, without manifest delta waves, are not uncommon. Absence of anterograde preexcitation, therefore, indicates neither that the accessory connection is no longer present, nor that the patient is no longer susceptible to tachycardia. The patient may still have retrograde conduction, which allows for atrioventricular reciprocating tachycardia. Patients with Ebstein's malformation may still have Wolff-Parkinson-White syndrome, a manifest delta wave, and a paradoxically normal PR interval. In these patients, the PR interval is artificially lengthened by delayed conduction through the large right atrium. The presence of left axis deviation in a patient with Ebstein's malformation suggests the presence of the Mahaim variant of preexcitation, produced by atriofascicular tracts.⁴⁶

Arrhythmias in the non-neonatal, unoperated patient with Ebstein's malformation are common.⁴⁷ Almost four-fifths of preoperative patients in this series either had documented arrhythmias, or histories of palpitations, near-syncope, or syncope. In those with documented arrhythmias, half had paroxysmal supraventricular tachycardia, one-quarter had paroxysmal atrial fibrillation or flutter, another quarter had ventricular arrhythmias, either with frequent ventricular premature complexes or nonsustained ventricular tachycardia, and one-tenth had some form of atrioventricular block. Of those with ventricular arrhythmias, one-third also had paroxysmal supraventricular tachycardia, another third had paroxysmal atrial fibrillation or flutter, and one had complete heart block. The patients with arrhythmias or symptoms compatible with arrhythmia were significantly older than those without symptoms or arrhythmias.

Even prior to the widespread application of complex surgical antiarrhythmic procedures, surgical intervention appeared to decrease the frequency of arrhythmias, at least

in early, short-term follow-up. Review of a large series of patients treated at the Mayo Clinic, as yet unpublished, before and after definitive repair of Ebstein's malformation has revealed arrhythmias in just over two-fifths after operative repair compared with three-fifths preoperatively. Supraventricular tachycardias decreased from one-half to one-quarter postoperatively. In one-sixth of the cohort, an accessory pathway was ablated at the time of repair or replacement of the tricuspid valve and closure of the interatrial communication, with no evidence of postoperative complete heart block. Despite the overall reduction in arrhythmias, when arrhythmias were observed early during postoperative recovery, these patients had an increased risk of late sudden death.

Introduction of more extensive antiarrhythmic surgery seems to improve results even further. Greason and colleagues⁴⁸ reported their results using the right atrial maze procedure for atrial arrhythmias in patients with congenitally malformed hearts, and seven-tenths of their cohort had Ebstein's malformation. Only one patient, with severe anatomic disease and multiple arrhythmias, did not survive the operation. Of the overall group, five-sixths remained in sinus rhythm at a mean of 17 months postoperatively. Only 6% had recurrent atrial fibrillation or flutter, albeit that 8% were in junctional rhythm, but only one patient required long-term pacing.

Chest Radiography

The cardiac size may vary from near normal to extreme cardiomegaly. When the heart is severely dilated, it takes on a globular shape that is similar to that seen with large pericardial effusions or severe dilated cardiomyopathy (Fig. 34-18A). There may be a dramatic change from preoperative to postoperative radiographs (Fig. 34-18B). The dilated right atrium is responsible for most of the enlarged cardiac silhouette. In the frontal view, the right atrium produces a significant convexity of the right heart border, and in the lateral view, the right atrium may fill the entire retrosternal space. The convex left border is primarily due to dilation of the right ventricular outflow tract. The convexities of both left and right heart borders produce the characteristic globular cardiac silhouette. In cyanotic

Figure 34-18 These two chest X-rays were taken from the same infant with severe Ebstein's malformation before (A) and after (B) repair of the tricuspid valve, right atrial reduction, closure of arterial duct, and partial closure of the atrial septal defect. Preoperatively, the heart nearly fills the chest on this frontal view, with the globular appearance reminiscent of a large pericardial effusion. Although the heart is still significantly enlarged after surgery, the cardiac volume has been markedly decreased, allowing improvement in both cardiac and lung function.

patients with a right-to-left shunt, the pulmonary vascularity is decreased. Otherwise, it is usually normal. In the asymptomatic patient, it is not unusual for the heart to have a normal size and shape. This may confuse the clinical diagnosis.

Echocardiography

Echocardiography has become the procedure of choice for both the diagnosis and long-term assessment of patients with Ebstein's malformation. In the 1980s, cross sectional echocardiography replaced M-mode as the clinical standard.^{49–51} As early as 1984, cross sectional imaging was considered sufficiently comprehensive that angiography was no longer necessary to diagnose Ebstein's malformation.¹⁰ Imaging of the internal cardiac crux, the components of the abnormal tricuspid valve, and the right ventricular myocardium reveal several features that are reliably used to identify patients with Ebstein's malformation. The single most sensitive and specific diagnostic feature is the displacement of the annular hinge of the septal leaflet. This displacement is most easily appreciated by comparison to the annular hinge of the mitral leaflet as seen in the apical four-chamber view. Even the septal leaflet of the normal tricuspid valve inserts at a position that is slightly apical to the insertion of the mitral valve. In patients with Ebstein's malformation, this displacement is exaggerated. The distance between the valvar hinge points can easily be measured (see Fig. 34-4). This distance, when divided by the body surface area in square meters, is known as the displacement index. In a heart with evidence of failed delamination, an index value greater than 8 mm/m² reliably distinguishes those with Ebstein's malformation from both normals and from patients with other disorders associated with enlargement of the right ventricle.^{10,49}

Occasionally, it can be difficult to assess the off-set between the valvar hinges at the internal crux. Other echocardiographic features can then help in diagnosis, including elongation of the anterosuperior leaflet, tethering of any of the leaflets to the underlying myocardium, shortened cordal support, attachment of the leading edge of the

anterosuperior leaflet to the right ventricular myocardium, displacement of the annular attachment of the anterosuperior leaflet, absence of the septal or mural leaflets, congenital fenestration of the leaflets, and enlargement of the valvar annulus.

Echocardiography is also used to define suitability for valvar repair, associated cardiovascular abnormalities, and myocardial function. There are several anatomic features of the valvar apparatus that indicate good candidacy for mono-leaflet repair, to be discussed at length later in this chapter. The most important determinant of a durable mono-leaflet repair is a freely mobile anterosuperior leaflet, especially its leading edge. The mobile leaflet tissue should be visualized within the right ventricular inflow tract, and this assessment must be made in the apical four-chamber view (Fig. 34-19). Extensive adherence of more than half of the anterosuperior leaflet to the ventricular myocardium (see Fig. 34-14) makes a successful repair unlikely. A single central jet of regurgitation is more easily eliminated than are multiple regurgitant orifices (Fig. 34-20). Even when there is a significant amount of leaflet tissue present, direct muscular insertions from the ventricular free wall into the body of the anterosuperior leaflet can make repair impossible (Fig. 34-21).

The functional impact of the malformation of the right ventricle and tricuspid valve should be determined. Anatomic and functional severities are usually similar, but they are not always the same. For example, a patient can have a severe anatomic displacement with Ebstein's malformation but only mild functional impairment. This can occur if the interatrial communication is small, the displaced valve is relatively competent, and the myocardium is only mildly dysfunctional. Both aspects of severity play an important role in determining functional state, prognosis, and reparability of the tricuspid valve.¹⁰ The degree of right atrial and ventricular enlargement and functional state of the right ventricular myocardium should also be defined.⁵⁰ Other important features include the degree of dilation of the right ventricular outflow tract, the presence and size of any atrial septal defect, and the degree of transvalvar regurgitation.^{10,51} The left ventricular myocardium has also been described as being abnormal in a significant fraction of the patients with

Figure 34-19 The three panels of this figure are all apical four-chamber inflow images of the same patient with Ebstein's malformation. The left frame is from mid-diastole. The middle and right frames are from mid- and end-systole, respectively. Features that suggest favorable anatomy for mono-leaflet repair are that the anterosuperior leaflet in this patient is freely mobile, including its leading edge (arrows). There are no muscular insertions that limit or distort the motion of the valve. The regurgitant jet originated only from the gap in coaptation seen between the anterosuperior leaflet and the remnant of the septal leaflet. The leading edge of the valve reaches a point near enough to the septum that, given the degree of annular dilation, an annuloplasty can advance it to a point where it will coapt with the septum and the vestiges of the septal leaflet. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. (Modified from Cetta F, Edwards WD, Seward JB, et al: Congenital heart disease. In Vannan MA, Lang RM, Rakowski H, Tajik AJ [eds]: *Atlas of Echocardiography*. Philadelphia: Current Medicine LLC, 2005.)

Figure 34-20 These apical four-chamber images show two patients with Ebstein's malformation. The case illustrated in the upper panels shows a valve that is freely mobile (*upper left panel*) and colour flow mapping (*upper right panel*) revealed that there was only a single, central jet of regurgitation. This patient subsequently had a successful valve repair with only mild residual tricuspid regurgitation and no stenosis. The case shown in the lower panels displays a large muscular insertion to the middle of the anterosuperior leaflet (*lower left*) and multiple fenestrations and sites of regurgitation. The tethering and multiple origins of regurgitant flow dramatically decrease the chance for successful repair. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. (Modified from Cetta F, Edwards WD, Seward JB, et al: Congenital heart disease. In Vannan MA, Lang RM, Rakowski H, Tajik AJ [eds]: Atlas of Echocardiography. Philadelphia: Current Medicine LLC, 2005.)

Ebstein's malformation.^{26,35,52,53} Quantitative evaluation of left ventricular performance, therefore, should also be a routine component of the echocardiographic evaluation of the patient with Ebstein's malformation. Defects such as ventricular septal defects and pulmonary stenosis may also be found in association with Ebstein's malformation. Doppler and colour flow echocardiographic assessment can help determine haemodynamic alterations such as valvar regurgitation and intracardiac shunting. Additional experience with, and follow up after, the cone reconstruction⁴⁹ of the tricuspid valve is needed before we can confidently define the anatomic features associated with favourable results from this procedure.

Echocardiography also plays an important role intraoperatively and postoperatively in assessing adequacy of tricuspid valvar repair or replacement.^{50,51} The most important use of intraoperative echocardiography is the immediate evaluation of the repaired valve. A repair that is not functioning can be revised, or else the valve can be replaced without a repeat operation. The post-operative examination can also be used to assess prosthetic valvar function and changes in right and left ventricular function and to exclude significant residual atrial level shunting. Similarly, post-operative echocardiography is important not only to assess the adequacy of the surgical repair, but also to exclude post-operative complications, including pericardial or pleural effusion, mediastinal haematoma, and intracardiac thrombus. The degree of residual tricuspid regurgitation or tricuspid stenosis should be determined. Assessment of ventricular function and regional abnormalities of wall motion plays an important role. Rarely, flow can be compromised in the right coronary artery because

Figure 34-21 The arrows in this apical four-chamber image point to significant, direct muscular insertions from the right ventricular free wall into the midsection of the anterosuperior leaflet of the tricuspid valve. Even though this valve leaflet has separated from the underlying myocardium, its mobility was quite limited by these attachments to the ventricular free wall. aRV, anterior right ventricle; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

of its proximity to the plicated portion of the atrialised right ventricle.

Prenatal Detection of Ebstein's Malformation

Echocardiography can accurately define the features of Ebstein's malformation in the fetus. Characteristics that have been identified with early neonatal mortality include marked enlargement of the right heart, severe tethering of the anterosuperior leaflet, left ventricular compression, and associated lesions such as pulmonary atresia.⁵² Pulmonary hypoplasia develops secondary to severe cardiomegaly and hydrops with pleural and pericardial effusions. Detection of disturbances of rhythm, such as supraventricular tachycardia, should be attempted at the time of fetal echocardiography because they can contribute to the development of hydrops. Finding the ratio of the combined right atrial and atrialised ventricular area compared to the combined area of the functional right ventricle and left heart to be greater than 1 was shown to be associated with very poor fetal or neonatal outcome.⁵³ Other fetal or neonatal findings that were associated with increased risk of mortality were a larger atrial septal defect, functional or anatomic pulmonary atresia, or reduced left ventricular function.

Exercise Testing

Exercise testing has become one of the routine noninvasive studies used to evaluate patients with Ebstein's malformation, both before and after surgical intervention. Studies performed before and after surgery have revealed several interesting findings.^{54–56} In the largest of these series,⁵⁶ unoperated patients had significantly reduced indexes of exercise tolerance for work, duration, and maximal oxygen uptake. In post-operative patients, these indexes all increased and approached the lower limits of normal. Arterial saturations of oxygen both at rest and during exercise were significantly lower in unoperated than in post-operative patients, undoubtedly due to closure of the atrial septal defect. In the unoperated patient, progressively lower saturations at rest and at maximum exercise were associated with progressively reduced exercise tolerance. Surgical intervention improved exercise tolerance. Most post-operative patients had resting and exercise cardiac outputs that were similar to the normal population. Patients with an atrial septal defect and right-to-left shunting demonstrated excessive ventilation at rest and during exercise. In these patients, a right-to-left shunt is a strong stimulus to increased ventilation.

Cardiac Catheterisation and Haemodynamics

In the early days of intracardiac investigation, it became evident that patients with Ebstein's malformation were at increased risk during catheterisation. Concerns about the safety of cardiac catheterisation in these patients have now been dispelled by modern techniques of monitoring the haemodynamic state during the study, more flexible catheter materials, and the availability of effective treatment for arrhythmias provoked by manipulation of the catheter. Even though patients with Ebstein's malformation can now be safely studied, the need to do so arises infrequently, such as when there are clinical questions regarding pulmonary arterial resistance.

There is usually moderate elevation of the right atrial pressure, often with a dominant V wave and steep Y descent. When the right atrium is massively dilated, the atrial pressure may be normal in spite of severe tricuspid regurgitation. Most often, the right ventricular pressures are normal, but in some the end-diastolic pressure may be elevated. Generally, the pulmonary arterial pressure is normal, but it may be decreased in those with severe tricuspid regurgitation and right-to-left shunting. In those with an atrial septal defect, right-to-left shunting will result in systemic arterial desaturation. Historically significant is a technique of simultaneously recording the intracavitary pressure and intracardiac electrogram tracing. When a catheter with an end hole and an electrode at the tip was positioned in the atrialised portion of the right ventricle, the pressure tracing recorded was atrial, but the electrogram showed ventricular activity. This was one of the earliest methods used confidently to make a diagnosis of Ebstein's malformation.

Angiocardiography

Except in its mildest forms, right ventricular angiocardiography is usually diagnostic of Ebstein's malformation. In the frontal plane, injection of contrast medium in the right ventricle will demonstrate tricuspid regurgitation, a large sail-like anterosuperior leaflet, and frequently a distinct notch at the inferior cardiac border to the left of the spine. The notch is created by the displaced tricuspid valve, and marks the point of division between the atrialised and functional zones of the right ventricle. Frequently, a trilobed appearance occurs as a result of contrast medium outlining the enlarged right atrium, atrialised ventricle, and the outflow portion of the functional ventricle. The presence of the associated defects can be demonstrated by angiocardiography. Injection of contrast medium into the right ventricle of a cyanotic newborn with Ebstein's malformation may show tricuspid regurgitation and little or no contrast medium in the pulmonary arteries. This same finding may occur in the absence of anatomic obstruction if the pulmonary resistance is elevated. Patency of the right ventricular outflow tract should be established by other techniques, such as advancement of the catheter through a patent pulmonary valve, or injection of contrast medium in the arterial duct to show contrast medium filling the pulmonary trunk and regurgitating into the right ventricle.

Invasive Electrophysiology

Echocardiographic evaluation of anatomy is so accurate that diagnosis of Ebstein's malformation no longer depends on catheterisation and angiocardiography. Invasive electrophysiologic testing and catheter ablation, however, maintain their importance. The Pediatric Electrophysiology Society reported 65 patients with Ebstein's malformation that had invasive studies and attempted radio-frequency ablations.⁵⁷ Tachycardia mediated via an accessory pathway was very common, with only one-tenth having other mechanisms for their tachyarrhythmias. The pathways were right-sided or septal in the majority of patients with re-entrant arrhythmias, with only 4% being left-sided. In three-tenths, the patients had multiple pathways. Radio-frequency ablation was able temporarily to eliminate the tachycardia in almost nine-tenths of cases, depending on its mechanism, albeit that recurrence was common. Long-term success was achieved in only one-third in this early series.

More specific delineation of the anatomy of accessory conduction pathways in Ebstein's malformation has been provided by Olson and colleagues.^{58,59} In their series, the pathways were localised to the right inferolateral free wall in 11 patients, to the inferior paraseptal area in 9, and to both the septum and right free wall in 4. One patient had a right anterolateral connection. The mechanisms of arrhythmia included orthodromic reciprocating tachycardia in 15 patients, both orthodromic and antidromic reciprocating tachycardia in 4, inducible atrial flutter or fibrillation in 7, atrioventricular nodal re-entry in 2, and ventricular tachycardia in 1. All of these patients had surgical pathway ablations. None had recurrence of a tachycardia mediated through an accessory pathway during follow-up lasting for 4 years. Early results of the right-sided atrial maze procedure have also been encouraging in patients with Ebstein's malformation.^{45,60,61}

Clinical Course and Treatment of Patients with Ebstein's Malformation

Natural History, Pregnancy and Risks of Recurrence

The outcome of Ebstein's malformation depends a great deal on the age of the patient at presentation, the severity of the lesion, and the presence of associated defects, these features being inter-related. Severely affected fetuses or neonates can easily be detected with echocardiography. As a result of their severe disease, they generally have a poor outcome.⁹ In one series, all neonates died when the combined area of the right atrium and atrialised right ventricle was greater than the combined area of the functional right ventricle, left atrium, and left ventricle.⁶² Mild disease in neonates and young children has a relatively good outcome, depending primarily on the presence of associated lesions.

The natural history of Ebstein's malformation was first reviewed by Watson in 1974.⁷ In this international cooperative study, 505 patients were collected from 61 centers in 28 countries. Only 35 patients were less than 1 year old, 403 were between 1 and 25 years, and 67 were over 25 years. Cardiac failure was present in almost three-quarters of infants. In contrast, four-fifths of the patients presenting at older ages were said to have had normal growth and development during infancy. Also, almost three-quarters of the patients aged from 1 to 25 years and three-fifths of those older than 25 years had little or no disability at the time of diagnosis and were placed in the first or second categories of the classification of the New York Heart Association. Catheterisations had been undertaken on 363 patients, with 13 deaths and 6 cardiac arrests that were treated successfully. Paroxysmal tachycardia occurred during the catheterisation in 90 patients. Of the overall cohort, 77 (15.2%) died secondary to medical complications of the disease. After an initial higher risk of death in the neonatal period, the hazard for death was similar among all those aged greater than 1 year. Of the 403 patients aged between 1 and 25 years, 50 (12.4%) died of the disease. Half of the deaths were due to cardiac failure, with one-fifth dying suddenly, presumably due to an arrhythmia. In those over 25 years, 11 of 67 patients (16.4%) died of natural causes, 2 from congestive cardiac failure and 2 suddenly.

In 1994, Celermajer and colleagues described 220 cases of Ebstein's malformation presenting from fetus to

adulthood (see Table 34-1).⁹ The median age at time of presentation had decreased to less than 1 year, emphasising the role echocardiography now plays in early diagnosis. Neonatal mortality was due to cardiac failure and pulmonary hypoplasia, secondary to cardiomegaly. Associated cardiac defects were more common in patients who presented early. Those newborns with the isolated form of the malformation usually showed spontaneous improvement as the pulmonary vascular resistance decreased. Patients diagnosed later in childhood tended to present with a cardiac murmur discovered incidentally. Arrhythmias and progressive desaturation due to right-to-left shunting were more common in the older child and adult.

Women with Ebstein's malformation can tolerate pregnancy, particularly when their functional state is good prior to commencement of the pregnancy.⁶³⁻⁶⁵ As a group, nonetheless, there is an increased risk of fetal demise and prematurity in mothers who had more significant disease.⁶⁶⁻⁶⁸ In 1994, Connolly and Warnes reported a comprehensive review of pregnancy outcome in patients with Ebstein's malformation, analyzing histories of pregnancies in 72 couples in which one member, 44 women and 28 men, had Ebstein's malformation.⁶⁹ Pregnancy seemed well tolerated by the affected mothers but was associated with an increased risk of prematurity, fetal loss, and congenital cardiac disease in the offspring. The rates of miscarriage and fetal loss were 18%, slightly higher than the expected age-matched rates of 10% to 15%. Infants born to cyanotic women had significantly lower birth weights than did those born to noncyanotic mothers. Congenital cardiac disease was found in 6% of the offspring of the women with Ebstein's malformation but was found in only 1 of the 75 children (1.3%) born to couples in whom the man had the malformation. The incidence of Ebstein's malformation in the offspring was 0.6%, occurring in only 1 of the 158 children born to the couples. There were no significant maternal complications or death, suggesting that women with Ebstein's malformation tolerate pregnancy well. Maternal arrhythmias and cyanosis, of course, warrant close observation during the pregnancy.

Medical Therapy

Patients with Ebstein's malformation display a wide spectrum of haemodynamic abnormalities and arrhythmias that can occur at a variety of ages. Because of this, no dogmatic recommendations can be applied. It is possible to assemble general guidelines for treatment. At one end of the spectrum are patients with mild anatomic abnormalities, relatively normal haemodynamics, and no symptoms. These patients require only observation and normal precautions to prevent bacterial endocarditis. Beyond this, the anatomic and haemodynamic abnormalities may become important enough to cause symptoms and significantly alter lifestyle. For these patients, surgical therapy is often the most effective treatment.

Treatment of the critically ill neonate with Ebstein's malformation involves use of prostaglandin E₁ to maintain patency of the arterial duct, and the use of pulmonary vasodilators. High levels of inspired oxygen, nitric oxide and occasionally sildenafil, epoprostenol, or tolazoline, are also used. Many babies improve spontaneously as the pulmonary vascular resistance falls, with consequent improvement in forward flow through the tricuspid valve and right ventricular outflow, and reduced right-to-left

shunting at atrial level. Intensive support, including ventilation, may be required during the first few days to weeks. If cyanosis is caused by associated structural obstruction of the right ventricular outflow tract, palliative surgery is indicated.

Many older children and adults are asymptomatic and can be managed conservatively. Exceptions include those with symptomatic arrhythmias, poor exercise tolerance, significant resting or exertional cyanosis, or symptoms of cardiac failure. Arrhythmias in general are difficult to treat. Accurate diagnosis should be obtained by 12-lead or ambulatory electrocardiographic monitoring, or home telemetry devices if necessary. Drug-refractory patients, or those with syncope, should have detailed electrophysiological studies. Over half the patients require a trial of two or more antiarrhythmic agents to obtain reasonable symptomatic control with medications.⁷⁰ Digoxin is useful for controlling the rate of response of the ventricles in those with atrial fibrillation, but is relatively contraindicated in patients with pre-excitation. Radio-frequency ablation may prove an effective alternative for those with accessory atrioventricular connections, although the procedure may be complicated by the presence of multiple pathways, the enlarged right atrium and the distorted anatomy of the tricuspid valve.

Cardiac failure may be treated with diuretics, and afterload reduction is appropriate for those with known left ventricular dysfunction. Oral anticoagulation is advisable for any patient with paroxysmal or chronic atrial fibrillation or flutter, except in those with a bleeding diathesis or other contraindication.

Most patients in the first or second functional classes, with mild or no cardiomegaly, can be managed medically. Operative correction is generally reserved for those with progressing symptoms, increasing cyanosis, or intractable arrhythmias requiring surgical elimination, or if paradoxical embolism occurs. Operation should also be considered if there is objective evidence of deterioration, such as decreasing exercise performance by exercise testing, progressive increase in the size of the heart on the chest radiograph, progressive right ventricular dilation, or reduction of systolic function, by echocardiography, or inadequate control of atrial or ventricular arrhythmias. In borderline situations, echocardiographic images demonstrating features favourable for valvar repair make the decision to proceed with operation easier.

Once symptoms develop and progress such that the patient is in the third or fourth functional classes, medical management has little to offer. Operation then becomes the only chance for improvement. A biventricular repair is usually possible, but in some circumstances, such as when significant left ventricular dysfunction has developed, cardiac transplantation may be the best option.

Surgery for Ebstein's Malformation

Palliative operations, such as construction of a systemic-to-pulmonary arterial shunt, a bidirectional Glenn anastomosis, or pulmonary valvotomy, may be required for neonates and infants with persistent cyanosis associated with structural pulmonary stenosis or atresia. In general, these procedures can be performed with low risk.⁷¹ Open heart surgery for the symptomatic neonate usually consists of either a biventricular repair⁷² or a functionally univentricular strategy.¹¹ The neonatal biventricular repair typically

consists of repair of the tricuspid valve with subtotal closure of the atrial septal defect. The functionally univentricular strategy consists of an initial operation to close the tricuspid valve with a patch, atrial septectomy, and construction of a systemic-to-pulmonary arterial shunt. The second stage includes construction of a bidirectional Glenn anastomosis at 3 to 6 months of age and conversion to the Fontan circulation at 2 to 4 years of age. Occasionally, surgery for repair of associated defects is indicated in isolation, such as closure of an atrial septal defect in the setting of left-to-right shunting, closure of an associated ventricular septal defect, or isolated surgery to cure arrhythmias.

Indications for surgery include symptoms, cyanosis, decreased exercise tolerance, poor growth, the presence of an atrial septal defect, paradoxical embolism, increasing cardiomegaly, and onset or progression of atrial tachyarrhythmias. Operation is considered in asymptomatic patients who have anatomy that would have high probability of successful repair. Early^{11,73,74} and intermediate^{49,75-78} results have produced good to excellent outcomes.

The anatomy of the valve that is ideal for monoleaflet repair includes greater than half of the anterosuperior leaflet being free from tethering to the ventricular wall, and the leaflet possessing a free and mobile leading edge. The presence of leaflet tissue adjacent to the pulmonary valve in a short-axis view indicates severe displacement, and makes successful repair less likely (Fig. 34-22). Additional delamination of the septal and/or mural leaflets provides a more promising situation for successful repair. In complex cases, replacement of the valve may be required.

The optimal technique for valvar reconstruction has yet to be established since the first report by Hardy in 1964. Contemporary techniques commonly used include those of Danielson,^{73,77,79-81} and most recently Da Silva.⁴⁹

Each method of repair typically incorporates selective plication or resection of the atrialised right ventricle, especially when it is thin-walled and moves paradoxically. A current technique has been proposed that moves the tricuspid valve to an anatomic position, the so-called cone reconstruction.⁴⁹ The surgeons from the Deutsches Herzzentrum have long used the monoleaflet approach, but without resorting to plication of the atrialised inlet component.⁸² Results of these procedures have been good for selected older children and adults, with an early mortality rate of 5%. Good results, with slightly higher mortality rates of 10%, have also been reported for the repair devised by Carpentier and colleagues,⁸¹ which involves longitudinal plication of the atrialised right ventricle and tricuspid annuloplasty, with or without placement of an annuloplasty ring.²² A similar approach has been used by Quaegebeur and colleagues,⁸³ and more recently by Chen and colleagues.⁷⁶ Most survivors of repair achieve good functional state, and have improved exercise performance.^{84,85} In a proportion of patients who come to surgery, the morphology or immobility of the anterosuperior leaflet is deemed to prevent repair, and replacement is required.⁷¹ The number of such patients often reflects the skill of the surgeons in reparative procedures, with less than 3% of those patients referred to Hôpital Broussais requiring valvar replacement.²² When replacement is necessary, the abnormal leaflet tissue in the right ventricular outflow tract is excised in order to prevent obstruction. In addition, care is made to preserve the membranous septum and conduction tissue. Whether the

Figure 34-22 These two parasternal echocardiographic images (long axis to the left and an oblique view of the right ventricular outflow tract to the right) demonstrate extreme displacement of the tricuspid valve apparatus into the right ventricular outflow tract or infundibulum (*long arrows*). The short arrows show the septal hinge point of the pulmonary valve. When the tricuspid valve is so severely displaced, only the infundibulum is downstream from the displaced functional orifice. Successful valve repair would be difficult in this case. Ao, aorta; LA, left atrium; LV, left ventricle; RV, right ventricle; RVOT, right ventricular outflow tract.

coronary sinus is left to drain above or below the prosthesis is determined by its proximity to the conduction tissue.⁷⁸ Many types of prostheses have been used, including Dacron-mounted allograft pulmonary valves,⁷¹ dura mater prostheses,⁸⁶ large heterograft valves, or mechanical prostheses in adults.⁸⁷ In the current era, it is our practice to utilise a porcine bioprosthesis when we need to replace the valve because of good durability,⁷⁸ and the lack of a need for warfarin anticoagulation. Reoperation, however, is inevitable in these patients. Although some have reported peri-operative mortality rates in these patients of up to 15% to 20%,⁷¹ in our experience it has been less than 5%. We have reserved replacement with a mechanical prosthesis for rare circumstances, specifically the presence of a left-sided mechanical prosthesis. Caution should be exercised with the use of a mechanical valve when there is significant right ventricular dysfunction, since the motion of the disc may be abnormal, and the risk of thrombosis may be increased, even in the presence of warfarin anticoagulation.

Another factor that has recently received much attention is the role of the bidirectional Glenn anastomosis as part of the so-called one and a half ventricle repair for Ebstein's malformation. While some have proposed routine use of the Glenn anastomosis,⁸⁸ we have utilised it only in selective circumstances. In patients with Ebstein's malformation and impaired right ventricular function, the bidirectional Glenn may facilitate operation by unloading the enlarged and dysfunctional right ventricle, and provide preload to the left ventricle.⁷⁴ In addition, if the size of the functional right ventricle is felt to be small, which is rarely the case, or the tricuspid repair results in a small valvar orifice, then a bidirectional Glenn anastomosis becomes an option. Rarely is a Fontan-type operation required when the first operation is beyond the neonatal period.

Atrial tachyarrhythmias commonly co-exist. A concomitant maze procedure is then recommended at the time of repair of the Ebstein's malformation.^{45,60} Accessory conduction pathways producing the Wolff-Parkinson-White syndrome are present in approximately one-sixth of patients with Ebstein's malformation. In the current era, electrophysiologic study and ablation in the catheterisation laboratory are the norm. Intraoperative mapping and ablation are reserved for an unsuccessful percutaneous approach.

Less common arrhythmias, such as atrioventricular nodal re-entry tachycardia, are also treated in the catheterisation laboratory. Surgical treatment is indicated only when transcatheter treatment has been unsuccessful. In some circumstances, surgical treatment has been performed when operation for Ebstein's malformation is required anyway.

In our experience, we have been able to perform a biven-tricular or one and a half ventricle repair for most of our patients, with an operative mortality of less than 5%. It is very rare for orthotopic cardiac transplantation to be necessary as the first method of treatment. Circumstances when it may be considered include the presence of severe biven-tricular dysfunction.^{12,74}

OTHER TRICUSPID VALVAR ABNORMALITIES

Tricuspid Valvar Dysplasia

While dysplasia of the valvar leaflets is often an integral part of Ebstein's malformation, dysplastic leaflets can also be found when retaining their normal hinges at the atrio-ventricular junction (see Fig. 34-16). Such dysplasia of normally hinged leaflets can produce just as much valvar incompetence as Ebstein's malformation (Fig. 34-23).

In contrast to Ebstein's malformation, the myocardium in these hearts is usually normal, at least early in life. As a result, ventricular function is better preserved, and outcomes are more favorable. Isolated dysplasia can produce the same wall-to-wall heart,³⁰ with the same consequences for pulmonary problems in the neonatal period.²⁷

Other Abnormalities

Lesions associated with severe right ventricular enlargement, but having anatomically normal tricuspid valves, should not be mistaken for Ebstein's malformation or tricuspid valvar dysplasia. Traumatic rupture of the cordal support of the valve (Fig. 34-24), Uhl's malformation, and arrhythmogenic right ventricular cardiomyopathy have been misidentified as Ebstein's malformation in the past. Traumatic rupture of tricuspid cords can produce abnormal motion of the leaflets, severe regurgitation, and chamber enlargement. The leaflets, however, are not adherent to the myocardium, and the junctional hinges are normally

Figure 34-23 These echocardiographic images display a case of tricuspid valvar dysplasia. The upper panels are apical four-chamber images from a transoesophageal exam. The lower panels are parasagittal transgastric images of the right ventricular inlet. The tricuspid leaflets are thick and demonstrate reduced systolic motion. The leaflets cannot fully coapt in systole, and there is a large central jet of tricuspid regurgitation seen in both right hand panels (*arrows*). All segments of this valve have delaminated from the underlying myocardium. All of the annular hinge points are in their normal positions at the atrioventricular junction. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

Figure 34-24 These echocardiographic images demonstrate traumatic rupture of the cordal supports to the anterosuperior leaflet of an otherwise normal tricuspid valve. The patient was involved in a serious motor vehicle accident 20 years prior to this examination. The cause of his tricuspid regurgitation had been previously misidentified as Ebstein's malformation. The upper panels are apical four-chamber images, and the lower panels are parasternal images aligned with the right ventricular inlet. Both the anterosuperior and septal leaflets are fully delaminated, and their junctional hinges retain a normal position at the atrioventricular groove. The arrows highlight the flail nature of the anterosuperior leaflet. The leaflet abnormality correlates well with the severe regurgitation displayed in the corresponding color flow images to the right. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

positioned. In the lesion described by Uhl,²⁸ the tricuspid and pulmonary valves were both normal. The essence of the malformation is congenital absence of the parietal myocardium, histological analysis showing that the epicardial and endocardial layers of the wall lie edge-to-edge.²⁹ It is also a mistake to correlate fibro-fatty replacement of the right ventricular parietal walls with either Ebstein's malformation or Uhl's malformation. Fibro-fatty replacement is the essence of arrhythmogenic right ventricular cardiomyopathy, now recognised as a cardiomyopathy in its own right, with various genetic causes.

ACKNOWLEDGEMENTS

The authors gratefully acknowledge David S. Celermajer and John E. Deanfield for their efforts in preparation of the previous editions of this chapter, which we have relied on for guidance. We appreciate the assistance of Kim Feils and Sharon Long in the preparation of this chapter and the unique input of William D. Edwards for his anatomic insights and generosity in sharing his photographic examples. Lastly, we owe a tremendous debt to the contributions of Gordon K. Danielson to our understanding of the anatomy, pathophysiology and care of the patient with Ebstein's malformation.

This study reevaluated the frequency with which gestational exposure to lithium therapy was associated with development of Ebstein's malformation. Although the risk of any congenital malformation, not only cardiac, was two to three times that seen in nontreated mothers, there was no increase in the frequency of Ebstein's malformation relative to controls. This demonstrated that the relative risk of treatment with lithium during pregnancy is much less than was originally estimated from the retrospective case reports. The decision as to whether or not to continue such treatment during pregnancy must now be made by weighing the relative risk of teratogenicity against the risks of relapse of manic/depressive disease in the mother.

Taken together, the last four articles provide a comprehensive summary of the issues surrounding the surgical treatment of the patient with Ebstein's malformation. They cover indications for intervention, factors influencing the choice of surgical procedure, technical descriptions of reparative maneuvers as well as summaries of results.

CHAPTER 35

Anomalies of the Morphologically Mitral Valve

JEFFREY F. SMALLHORN and ROBERT H. ANDERSON

In this chapter, we discuss those lesions than afflict the morphologically mitral valve, the likeness to the episcopal mitre of this valve in the normal heart first being emphasised by Andreas Vesalius, the Belgian morphologist, who worked in Padova, the birthplace of cardiac morphology, in the 15th century. As with the episcopal headwear, the feature of the normally constructed mitral valve is the solitary zone of apposition between its component parts, the leaflets, this feature producing a bifoliate pattern of closure. The pattern of closure, in turn, distinguishes the normally structured left valve from the left half of the common valve seen in the setting of atrioventricular septal defect with common atrioventricular junction. Although similar lesions can affect the left-sided heart when there are separate or common atrioventricular junctions, the anomalies involving the left half of the common valve will be discussed in Chapter 27. We also reserve discussion of anomalies of the left-sided valves in hearts with double inlet ventricle for Chapter 31, despite the fact that, when there is double inlet to a dominant left ventricle, it is usual for both atrioventricular valves to resemble the morphologically mitral valve. Either the right-sided or left-sided valve, nonetheless, can be deformed in this setting. In this chapter, therefore, we confine our attention to the valve guarding the inlet to the morphologically left ventricle in hearts with separate right and left atrioventricular junctions. The lesions to be described that involve the morphologically mitral valve, therefore, can also involve this valve when both the atrioventricular and ventriculo-arterial connections are discordant. The latter malformation, best described as congenitally corrected transposition, will receive its own coverage in Chapter 39.

MORPHOLOGY

It is convenient, albeit not always entirely accurate, to describe the abnormal morphology in terms of malformation of the various components of the mitral valve, remembering that, in functional terms, such derangement can result in stenosis, incompetence, or both.¹⁻³ In terms of anatomy, we will discuss anomalies of the leaflets, the tension apparatus, and the papillary muscles, all of these components working in harmony when the valve is normal (Fig. 35-1). The leaflets are hinged from the annulus, but this is far from a constant structure in the mitral valve. Furthermore, as far as we are aware, there are no specific congenital lesions that afflict only the annulus. The hinges of the aortic and mural leaflets are markedly different in their structure. The hinge, or annulus, of the anterior

leaflet of the valve is the area of its fibrous continuity with the leaflets of the aortic valve, hence our preference to describe this leaflet of the valve as being aortic. The two ends of the region of fibrous continuity between the leaflets of the atrioventricular and arterial valves are themselves thickened as the right and left fibrous trigones. It is the anchorage of these trigones to the basal surface of the ventricular mass that secures the combined unit of the inlet and outlet valves within the left ventricle (Fig. 35-2). The part of the mitral valvar circumference formed by the aortic leaflet, therefore, is strong. It is much less likely to dilate under abnormal circumstances than the remaining part of the valve. This second part of the valve, the mural or posterior leaflet, is anchored along the parietal part of the left atrioventricular junction. There is marked variation in the arrangement of the mural annulus itself.⁴ In places, it is a firm fibrous cord that fits well with the notion of a ring (Fig. 35-3). It is unusual, nonetheless, for such a fibrous ring to support the entirety of the leaflet throughout the mural part of the valvar perimeter. In places, the cord is replaced by a longer fibrous sheet, or else the fibrous tissue becomes deficient, with the atrial and ventricular musculatures separated by fibroadipose tissue rather than a true annulus.⁴ Because of this variation, and the frequent lack of a complete fibrous ring, it is this part of the valvar circumference that dilates in

Figure 35-1 The long-axis section through the left ventricle, showing the parasternal echocardiographic view, illustrates the components of the mitral valvar complex that work in harmony when the valve is normal. The specimen was prepared subsequent to injection of fixative under pressure in the left ventricle, maintaining the systolic configuration of the leaflets.

Figure 35-2 The normal heart has been sectioned to replicate the echocardiographic short axis of the left ventricle. Note the thickening of the two ends of fibrous continuity between the leaflets of the aortic and mitral valves (purple dotted line) to form the fibrous trigones (red triangles). The fibrous continuity is the annulus of the aortic leaflet of the mitral valve, the mural leaflet being hinged along the parietal atrioventricular junction (see Fig. 35-3).

Figure 35-3 This section through the parietal part of the left atrioventricular junction shows how, in some instances, the mural leaflet of the mitral valve is hinged from a firm fibrous ring. The section is stained with Van Gieson's reagent, which shows the fibrous tissue, including the fibrous ventricular layer of the valvar leaflet. Note the thin layer on the atrial aspect of the leaflet, known as the spongy layer.

the setting of valvar disease. In such cases of acquired change, it is often the case that all parts of the valve are abnormal. We commence our account of morphology, therefore, by considering anomalies of the entire valvar apparatus.

Figure 35-4 This valve is from a patient with hypoplasia of the left heart. The entire valvar complex is miniaturised, and the leaflets are dysplastic.

Mitral Valvar Dysplasia and Hypoplasia

All components of the complex are malformed when the valve is dysplastic and hypoplastic. The leaflets are thickened, the intercaval spaces often obliterated and the papillary muscles deformed, the last frequently extending as muscular strands directly into the leaflets. Usually such a valve shows global hypoplasia, and is the most common lesion underscoring congenital mitral stenosis, be this isolated or as seen most frequently in the setting of hypoplasia of the left heart (Fig. 35-4).

When the free edges of the dysplastic valve leaflets are thickened and rolled, the valve may be incompetent as well as stenotic. Occasionally, mitral stenosis may be produced when the valve is hypoplastic and dysplastic.

Anomalies of the Leaflets

The most extreme anomaly involving the leaflets is an imperforate valve (Fig. 35-5). Such imperforate valves are seen most frequently in combination with aortic atresia, when they form part an integral part of the hypoplastic left ventricle syndrome (see Chapter 29). In this setting, from the stance of anatomy, the imperforate valve is distinguished from absence of the left atrioventricular connection (Fig. 35-6), since both produce atrioventricular valvar atresia. In the setting of left heart hypoplasia, of course, this morphological distinction is rarely, if ever, of clinical significance. In hypoplasia of the left heart, when the left atrioventricular connection is absent, the right atrium is connected to a dominant right ventricle. The left atrioventricular connection can also be absent when the right atrium is connected to a dominant left ventricle (Fig. 35-7). This lesion is best considered in the setting of the functionally univentricular heart (see Chapter 31). Imperforate mitral valves, of course, can also be found without aortic atresia (see Fig. 35-5), and are then part of the combination termed mitral atresia with patent aortic root.⁵ The ventriculo-arterial connection is often double outlet from

Figure 35-5 The leaflets of the mitral valve are formed, but fused to form an imperforate shelf. Note the papillary muscles supporting the ventricular aspect.

Figure 35-6 This dissection of the heart from a patient with hypoplastic left heart syndrome shows complete absence of the left atrioventricular connection. The right atrium is connected to a dominant right ventricle. Note the left coronary artery interposed between the blind-ending floor of the left atrium and the incomplete left ventricle.

Figure 35-7 This dissection, comparable to the one shown in Figure 35-6, shows absence of the left atrioventricular connection in the setting of the right atrium connected to a dominant left ventricle. It is now the right ventricle, positioned on the left shoulder of the ventricular mass, which is incomplete. Note that the right ventricle gives rise to the aorta, the ventriculo-arterial connections being discordant.

the right ventricle, but in a significant number of cases, the patent aorta arises from a good-sized left ventricle. The ventricle is then filled through a ventricular septal defect.

Ebstein's malformation can rarely affect the morphologically mitral valve.⁶ When this is the case, the mural leaflet is plastered down onto the ventricular wall, with its hinge below the atrioventricular junction (Fig. 35-8, left panel). In this setting, there is no thinning of the atrialised inlet portion, as is usually seen when it is the morphologically tricuspid valve that is deformed in the setting of concordant atrioventricular connections (Fig. 35-8, middle panel). Such lack of morphologic atrialisation is also a feature of Ebstein's malformation of the left-sided atrioventricular valve in the setting of congenitally corrected transposition, but then, of course, the valve itself is of tricuspid morphology (Fig. 35-8, right panel; see Chapter 39).

The isolated cleft is another anomaly confined to the leaflet, usually involving the leaflet in fibrous continuity with the leaflets of the aortic valve (Fig. 35-9). Well explained on the basis of failure of fusion between the left ventricular components of the superior and inferior atrioventricular cushions,⁷ the space between the cleft components of the leaflet creates the substrate for valvar incompetence. Both parts of the cleft leaflet tend to be dysplastic, and the edges are usually rolled and thickened (see Fig. 35-9). The cleft valve often co-exists with deficient ventricular septation, and the edges of the cleft are then frequently tethered to the crest of the ventricular septum by tendinous cords. The essence of these so-called isolated clefts of the aortic leaflet is that they are found in hearts with separate atrioventricular junction.^{8,9} The space between the edges of the cleft then points towards the subaortic outflow tract (Fig. 35-10), or to the antero-superiorly located interventricular communication when seen in the setting of the Taussig-Bing malformation. The lesion must be distinguished from the so-called cleft found in the left half of the atrioventricular valve of patients having atrioventricular septal defects with common atrioventricular junction (see Chapter 27). In the setting of the common junction,

Figure 35-8 The cartoon shows how, when Ebstein's malformation afflicts the morphologically mitral valve (*left panel*), it is the mural leaflet that is involved, and it is rare to find thinning of the atrialised ventricular inlet. When afflicting the morphologically tricuspid valve, the atrialised ventricular component usually shows marked thinning (*middle panel*), but such thinning is usually absent when the left-sided morphologically tricuspid valve shows Ebstein's malformation in the setting of discordant atrioventricular connections (*right panel*).

the so-called cleft is the zone of apposition between the left ventricular components of the leaflets that bridge the ventricular septum. This space points at the ventricular septum. Although the space between the leaflets is nowadays readily reconstituted by suture of its edges in both settings, it is only when there is a separate left atrioventricular junction that the surgical maneuver restores the morphology of a relatively normal mitral valve.

Another isolated anomaly of the valvar leaflets is the so-called funnel-shaped valve.¹⁰ This entity is characterised by thickening and retraction of the leaflets, with fused tendinous cords, but in the presence of normal papillary muscles. The funnel produces mitral stenosis. It is rare in postmortem collections. More common are valves with dual orifices. The dual orifices are produced by a tongue of valvar tissue that extends between the mural and aortic

leaflets, dividing the valvar orifice into two components, with each orifice then supported by one of the papillary muscles (*Fig. 35-11*). Dual orifices are more common within the left half of the atrioventricular valve of patients having atrioventricular septal defects with common atrioventricular junction (Chapter 27). As with the so-called cleft, these malformations should again be distinguished from those afflicting the bifoliate and otherwise normally structured mitral valve.

A rarer abnormality that can result in congenital mitral valvar regurgitation is hypoplasia of the mural leaflet, such that the valve leaflets cannot coapt normally during systole.¹¹ More frequent is straddling and overriding of the valvar leaflets. These anomalies can affect either the tricuspid or the mitral valve. Bridging of leaflets is also, of course,

Figure 35-9 There is a congenital cleft in the aortic leaflet of the mitral valve. Note that both parts of the cleft leaflet are dysplastic, and there is thickening of the tendinous cords (*arrow*).

Figure 35-10 In this heart with a cleft of the aortic leaflet of the mitral valve, there is also a perimembranous ventricular septal defect. Note that the edges of the cleft leaflet are attached by tendinous cords to the crest of the ventricular septum, and that the cleft itself points towards the aorta (*arrow*).

Figure 35-11 In this heart, a tongue of valvar tissue has joined together the aortic and mural leaflets of the mitral valve, producing dual valvar orifices (stars). Note that each orifice is supported by one of the paired papillary muscles of the valve.

Figure 35-12 In this heart with double outlet right ventricle and subpulmonary interventricular communication, the so-called Taussig-Bing malformation, there is straddling and overriding of the supero-anterior end of the zone of apposition between the aortic and mural leaflets, the papillary muscle being attached in the right ventricle.

a common feature of the common atrioventricular valve, albeit that a common valve can be exclusively connected to one or other of the ventricles. It is the spectrum between the commitment of straddling valves to one or other ventricle, underscoring the difference between functionally uni-ventricular and biventricular arrangements, which forms the focus of our chapter devoted specifically to straddling and overriding (see Chapter 33). When the morphologically mitral valve straddles and overrides, the valve always straddles through an antero-superior interventricular communication and is found with either discordant or double outlet ventriculo-arterial connections—the so-called Taussig-Bing malformation (Fig. 35-12).

When discussing malformations of the leaflets, we should also pay attention to a fibrous ridge that anchors together the aortic and mural components, narrowing the valvar orifice. Although usually described as a supra-valvar structure, the abnormal fibrous shelf is an integral part of the atrial surface of the leaflets,¹² and can readily be removed at surgery. Shelves can, indeed, exist within the left atrium, and produce true supra-valvar rings, but these are much rarer than the variant attached to the atrial aspect of the leaflets (Fig. 35-13).

Without question, the commonest lesion afflicting the leaflets of the mitral valve is prolapse. The problems concerning the pathology of prolapse of the mitral valve, however, are as numerous as those concerning its clinical features. There is no unanimity concerning nomenclature or aetiology and, perhaps more important, no standard definition of what precisely constitutes prolapse of the leaflets. The morphologist is under considerable constraint in this respect, since of necessity, in autopsy studies, the valve is viewed only in its fixed state. The morphologist

Figure 35-13 The cartoon, illustrating the parasternal long-axis section, shows the fundamental anatomic difference between a true supra-valvar left atrial ring and the so-called supra-valvar stenosing ring. The latter lesion is attached to the atrial surface of the valvar leaflets and should be considered an abnormality of the leaflets.

can only speculate on what might have happened as the valvar leaflets moved from their open diastolic position to the closed systolic pattern, unless the heart is fixed with pressure in the left ventricle so that the leaflets assume their systolic position (see Fig. 35-1). Much can be learnt concerning the mechanics of prolapse, nonetheless, by comparing the morphology of the prolapsing valve with the normal arrangement. The pathologist usually describes the

prolapsing variant as being floppy. Several pathological processes can produce a prolapsed leaflet as their end-point, such as ruptured tendinous cords secondary to ischaemic heart disease. The particular process producing the floppy valve is the one associated with the so-called click/murmur syndrome, this being the essence of the commonest form of mitral valvar prolapse. It is the mural leaflet that is most usually involved when the valve is floppy. The lesion may affect only one of its scallops (Fig. 35-14), but in severe cases the aortic leaflet may also be involved (Fig. 35-15).

Figure 35-14 In this heart, only the middle scallop of the mural leaflet of the mitral valve is prolapsing. Note the lack of cordal support to much of the scallop and the elongation of the persisting cords.

Figure 35-15 In this valve, removed at surgery, all parts of both leaflets are abnormal, and were prolapsing, albeit that the disease process afflicts the middle scallop of the mural leaflet most severely. Note the similarity of the valve to a parachute.

The affected leaflets are hooded, with their convexity to the left atrium. When the whole leaflet is involved, as is seen mostly in adults, the arrangement of the domed leaflets with their elongated cords takes on a parachute-like appearance, particularly when surgically removed (see Fig. 35-15). Pathologists dealing with disease of the adult population have described the valve in this fashion, but the choice of parachute is perhaps unfortunate in the setting of congenital cardiac malformations, since as we will see, the term is more usually used to describe malformations of the papillary muscles. Irrespective of the descriptions, when the leaflets are grossly prolapsed, there is little difficulty in recognition. Most floppy valves, nonetheless, are seen in adult patients, and in this setting it can be difficult to distinguish minimal prolapse from the normal arrangement. This may well be significant, since Becker and de Wit¹³ have pointed out that, in some normal valves, parts of the leading edge of the mural leaflet are less well supported by tendinous cords than other parts. They suggested that such an arrangement might predispose to prolapse, and subsequent observations confirmed that prolapsed segments of an affected leaflet are, indeed, less well supported than the non-prolapsed parts.¹⁴ The affected leaflets are markedly thickened, with myxomatous transformation of their atrial aspect. When the prolapse is marked, there is also dilation of the annulus, involving the attachment of the mural rather than the aortic leaflet. Part and parcel of the myxomatous proliferation of the spongy layer of the leaflet is an increased proliferation of acid mucopolysaccharides. These then impinge on the fibrous layer, with focal interruption. The end result is destruction of the fibrous core of the valve, some considering this to be the essence of the lesion.^{15,16} Histological studies of the abnormal leaflets, however, reveal no appreciable inflammatory reaction. It is the accumulation of acid mucopolysaccharides, with weakening of the fibrous core of the valve, along with the inequality of cordal support to the free edge of the affected valvar leaflet, therefore, which most probably account for the pathogenesis of prolapse. A myocardial factor has been proposed by many authors but is probably not of significance. The accumulation of acid mucopolysaccharide with weakening of the fibrous tissue and impaired collagen formation is seen typically in Marfan's syndrome, and it is no coincidence that prolapsed valvar leaflets are a well-recognised feature of this syndrome. Indeed, it has been suggested that isolated prolapse is an atypical form of Marfan's syndrome.¹⁷ As with so many controversies, the truth may well prove to lie between the two extremes, with disorders of both biochemical make-up and cordal support contributing to production of the floppy leaflets.

Anomalies of the Tension Apparatus

Anomalies of the tension apparatus include the lesions variously referred to as mitral arcade¹⁸ or hammock¹⁰ valve. These terms likely describe the same lesion, in which the papillary muscles extend directly to the edges of the leaflets (Fig. 35-16). In the most severe form, the muscles fuse on the leading edge of the aortic leaflet, forming the muscular arcade observed by the pathologist. When viewed from the atrial aspect, with the valve intact as seen by the surgeon, the intermixing of cords attached to the enlarged papillary muscle gives the appearance of a hammock. The abnormal

Figure 35-16 In this heart, the papillary muscles supporting the leaflets fuse along the leading edge of the aortic leaflet, producing a muscular arcade. Note also the obliteration of the intercordal spaces, which would have rendered the valve stenotic.

attachments produce mitral valvar insufficiency, but the morphologic appearance suggests that the valve would also be stenotic.

Anomalies of the Papillary Muscles

It is anomalies of the papillary muscles that produce the lesion most usually described by paediatric cardiologists and surgeons as being the parachute lesion, although it must be admitted that the valve malformed in this fashion bears appreciably less similarity to a parachute than the prolapsing valve (compare Figs. 35-17 and 35-15). There is also lack of agreement as to what produces the parachute malformation when the term is applied to the papillary muscles. The situation most closely resembling the parachute is seen when the two muscles are fused to produce a solitary mass (see Fig. 35-17). The alternative arrangement that has been likened to the parachute is seen when one papillary muscle, usually the anterolateral muscle, is grossly reduced in size or even, on occasions, totally absent. The tension apparatus then has a grossly eccentric appearance, effectively inserting into a solitary papillary muscle (Fig. 35-18). It was the latter arrangement, with a solitary papillary muscle, which was illustrated by Shone and colleagues¹⁹ when they introduced the term parachute mitral valve. This confusing situation was highlighted by Rosenquist,²⁰ who preferred to use the term to account for the arrangement with fused muscles. Furthermore, Carpentier and colleagues¹⁰ described fused papillary muscles as producing parachute valves. In the detailed study of Ruckman and Van Praagh,²¹ however, such cases were specifically excluded, since they did not fit the original illustration of

Figure 35-17 This abnormal mitral valve was removed at surgery. The papillary muscles are fused, and the tendinous cords are thickened. The arrangement of the papillary muscles bears some resemblance to a parachutist, but the open cavity of leaflets would be a lethal device!

Figure 35-18 In this malformed valve, from a patient with tricuspid atresia, all the tendinous cords insert to the infero-posterior papillary muscle of the mitral valve. Some describe this arrangement as the parachute malformation.

Shone and his colleagues.¹⁹ The form with fused papillary muscles, nonetheless, is more likely to be chosen by clinicians as their paradigm for the parachute malformation. For the morphologist, an absent or hypoplastic papillary muscle is readily recognised and described as such. Similar precision can also be provided by cross sectional echocardiography.²² So as to remove any confusion, when we speak of parachute valves, we will specify whether we are discussing the variant produced by fusion of the papillary muscles into a solid mass, often additionally dysplastic, or whether there is hypoplasia or absence of one or other of the papillary muscles.

Stenosis versus Incompetence

It is often difficult for the morphologist to predict from a specimen whether the observed pathology would have produced stenosis or incompetence. A much better appreciation is obtained by the surgeon.^{2,3,10} When insufficiency is the primary lesion, then this is most frequently the consequence of problems with the leaflets, exacerbated by dilation of the annulus. Alternatively, insufficiency as a primary feature can be caused by subvalvar problems, such as cordal retraction or elongation, or hypoplasia or agenesis of the papillary muscles. Prolapse is obviously the major substrate for many patients with mitral valvar problems. When stenosis is the major problem, this is likely to be a result of fusion along the ends of the zone of apposition between the leaflets of a dysplastic valve, a hammock lesion, a parachute deformity, or a funnel-shaped valve. Combined stenosis and insufficiency are related to fusion of the ends of the zone of apposition between the leaflets, a hammock valve, a parachute deformity, or papillary muscular hypertrophy.

Effect on the Heart

Valvar pathology always affects the cardiac pump and, despite compensatory mechanisms, may lead to serious side effects in the myocardium and endocardium. It should always be remembered that valvar pathology can also affect the pulmonary vascular bed, with pulmonary hypertension as a possible consequence.²³

DEVELOPMENT OF THE MORPHOLOGICALLY MITRAL VALVE

The atrioventricular junction comes into prominence following the rightward looping of the heart tube after the 25th day of gestation.⁷ By the end of the fifth week, the developing apical parts of the ventricles are visible, with the future left ventricle supporting the larger part of the circumference of the atrioventricular canal. The lumen of the atrioventricular canal is occupied by the inferior and superior endocardial cushions. Initially separate and discrete, these cushions eventually fuse during the sixth week, producing the right and left atrioventricular junctions, to which will be anchored the developing leaflets of the mitral and tricuspid valves. Parts of these fused cushions remain to the left side of the crest of the muscular ventricular septum, forming the scaffold of the aortic leaflet of the mitral valve.

Formation of the normal mitral valve can proceed only when the aorta becomes committed to the left ventricle, permitting the development of fibrous continuity between one of the leaflets of the mitral valve and two of the leaflets of the aortic valve, hence the name of aortic leaflet for the mitral component, which distinguishes it from its mural counterpart. Initially, there is still a cleft at the parietal margins of the site of fusion of the superior and inferior cushions within the left ventricle. The mural leaflet of the mitral valve is formed by protrusion and growth of a sheet of atrioventricular myocardium into the ventricular lumen, with subsequent formation of valvar mesenchyme on its surface, rather than by delamination of the lateral cushion from the ventricular myocardium, as was previously thought. The myocardial layer is then removed by apoptosis.²⁴ The aortic leaflet of the mitral valve, along with parts of the septal leaflet of the tricuspid valve, develops from mesenchyme of the superior and inferior atrioventricular cushions. Whereas the septal leaflet of the tricuspid valve delaminates from the ventricular myocardium, the aortic leaflet is never attached to, or supported, by the myocardium, except at its cranial and caudal margins, which develop with cordal and papillary muscular attachments to the left ventricular wall. Expansion of the inferior quadrants of the left atrioventricular junction involves growth of the parietal wall of the left ventricle, with comparable growth of the lateral cushion. This eventually results in the lateral cushion occupying two-thirds of the circumference of the developing mitral valvar orifice.

This expanded crescent is associated with compacting columns in the trabecular layer of the ventricular muscle, which eventually form the papillary muscles. Excessive or abnormal compaction of this trabecular layer of the developing ventricular myocardium is responsible for the parachute mitral valve. Failure of the formation of the tendinous chords from the myocardial primordiums results in the mitral arcade lesion, with muscle extending from the tips of the leaflets to the papillary muscles. When Ebstein's malformation of the mitral valve occurs, it is the mural leaflet that is involved, as this is the leaflet that excavates from the parietal ventricular wall.

Reciprocal signaling between the endocardial and myocardial cell layers in the cushion is mediated in part by members of the TGF- β family, and induces a transformation of endocardial cells into mesenchymal cells. Sox 9 is activated when myocardial cells undergo mesenchymal transformation. Sox 9 deficient mesenchymal cells fail to express ErbB3, which is required for proliferation of the cells within the endocardial cushions. The mesenchymal cells migrate into the cushions, and differentiate into the fibrous tissue of the valves. Several genes play a role in formation of the valvar leaflets, including calcineurin, with signalling and downstream activation dependent on the NFAT family of transcription factors. Absence of any of these genes results in fatal defects of valvar formation.²⁵

INCIDENCE AND AETIOLOGY

Congenital deformities of the mitral valve are rare, if those involving the left valve in hearts with common atrioventricular junction are excluded, with mitral stenosis occurring in 0.6% of postmortems and in 0.21% to 0.42% of clinical series.²⁶ Congenital mitral incompetence is even rarer.

There is a male to female ratio of around 1.5 to 1 to 2.2 to 1.^{26,27} Congenital mitral valvar anomalies are rarely isolated. The fully developed syndrome of so-called parachute mitral valve,¹⁹ for example, includes four obstructions within the left heart, namely the valvar lesion itself, supra-valvar mitral ring, subaortic stenosis and aortic coarctation. Any of these obstructions may co-exist with any congenital lesion afflicting the mitral valve, particularly coarctation. In a clinical series of patients with congenital mitral stenosis, excluding hypoplasia of the left heart, almost three-quarters had additional anomalies.²⁶ It is tempting to imagine that development of one abnormality upstream may, during morphogenesis, result in a series of more distal abnormalities owing to disturbance in the patterns of flow. Annular hypoplasia of the mitral valve is almost always associated with hypoplasia of the left ventricle and aortic stenosis or atresia. Ventricular septal defect is quite common in this setting, and double outlet right ventricle and tetralogy of Fallot occasionally occur. When the mitral valve is imperforate, left ventricular hypoplasia is inevitable unless there is an associated ventricular septal defect.²¹

PATHOPHYSIOLOGY

Supra-valvar mitral ring and congenital mitral stenosis are, by and large, indistinguishable in their effects. Unless specific differences are mentioned, they may be assumed to behave in the same way. Pure mitral stenosis, or imperforate mitral valve, results in a diastolic pressure difference between the left atrium and left ventricle with a consequent elevation of left atrial pressure. Patients in sinus rhythm, the great majority, have a tall a wave in the left atrial trace. Co-existence of an interatrial communication results in decompression of the left atrium. This may be so profound as to obscure or eliminate the transmitral pressure difference, even when the mitral valve is imperforate. By contrast, excessive flow through the mitral valve, as may result from an associated ventricular septal defect, will exaggerate the transmitral diastolic pressure difference. Elevation of the left atrial pressure usually results in reflex pulmonary vasoconstriction, particularly if the development of pulmonary oedema results in mismatch between ventilation and perfusion, and pulmonary venous hypoxaemia. The combined effect is to produce pulmonary hypertension. In the presence of associated patency of the arterial duct, or a ventricular septal defect, this can result in right-to-left shunting at an earlier age than would be expected were mitral obstruction not present. The rise in pulmonary vascular resistance, and consequent fall in pulmonary blood flow, means that, on sequential cardiac catheterisations in individuals with mitral stenosis, the gradient is frequently found to fall. This finding is similar to medical intervention using nitric oxide in patients with congenital mitral stenosis,²⁸ where it was observed that the pulmonary vaso-reactivity was greater than previously reported in adults. In the absence of pulmonary stenosis, and without any communication at great arterial or ventricular level, the pulmonary arterial systolic pressure may exceed systemic pressure. Right heart failure may then ensue. By contrast, severe pulmonary stenosis in the setting of a ventricular septal defect may mask entirely the effects of the valvar obstruction by reducing the flow of blood to the lungs. Left atrial pressure is bound to be lower than pulmonary arterial pressure,

irrespective of the severity of the mitral obstruction. Pure mitral insufficiency may cause left atrial hypertension with all the consequences already described. More commonly, considerable left atrial dilation occurs, with the result that left atrial hypertension is modest or non-existent. Cardiac output is maintained with a normal left ventricular ejection fraction by a modest increase in left ventricular end-systolic volume and a marked increase in left ventricular end-diastolic volume. This is not as striking as the increase in left atrial volume. The regurgitant fraction may be as high as 83%. Associated obstructive lesions downstream obviously increase the severity of the mitral regurgitation. In contrast to rheumatic mitral disease, the congenitally malformed mitral valve is usually either obstructed or regurgitant. An intermediate situation is produced in the rare case of mixed stenosis and incompetence.

CLINICAL PRESENTATION AND SYMPTOMATOLOGY

Congenital disease of the mitral valve usually presents as a result of the associated abnormalities, such as coarctation or ventricular septal defect. In these lesions, the symptoms are exacerbated by the presence of the mitral valvar problem, but this may be too subtle to detect. As already mentioned, the effects of the valvar anomaly are more or less neutralised by pulmonary stenosis and an interventricular communication. So, whatever the associated anomaly, the result tends to be that mitral disease is masked, and will not be recognised unless specially looked for. The presentation of isolated mitral valvar disease is largely determined by the height of the left atrial pressure. If this is normal, there are usually no symptoms at all. At most, there will be fatigue after severe exertion. A high left atrial pressure is likely to result in poor feeding, sweating in infancy, and failure to thrive. Patients with severe obstruction are likely to present in intractable cardiac failure in the first month or so of life. Orthopnoea is extremely rare, but patients frequently complain of a dry nocturnal cough. Wheezing and respiratory infections are frequent. Syncope, haemoptysis, or aphonia owing to compression of the recurrent laryngeal nerve by an enlarged left atrium, have occasionally been described. Pure mitral stenosis is characterised by poor nourishment, tachypnoea, and intercostal recession. There are normal-to-small peripheral arterial pulses, and the jugular venous pulse is also usually normal. If pulmonary hypertension is severe, a prominent a wave will reflect the raised right ventricular end-diastolic pressure. A systolic wave will demonstrate secondary tricuspid incompetence. Palpation of the heart will reveal either a normal impulse or right ventricular hypertrophy, and there may be an apical diastolic thrill. Pulmonary valvar closure will be palpable if pulmonary hypertension is severe. The first heart sound is either normal or loud and, in contrast to rheumatic mitral stenosis, an opening snap is only occasionally audible. Closure of the pulmonary valve is accentuated in patients with pulmonary hypertension. There is a loud low-pitched mid-diastolic murmur at the apex, usually with presystolic accentuation. Occasionally, no diastolic murmur is heard. In severe untreated disease, an early diastolic murmur of pulmonary incompetence and a pan-systolic murmur of tricuspid incompetence may be heard, both resulting from pulmonary hypertension. Crepitations may be heard

in the lung fields, but these are usually clear. Cyanosis is not seen unless there is severe pulmonary venous desaturation, or a right-to-left shunt through an associated defect.

PURE MITRAL INSUFFICIENCY

Most children are well nourished and in no distress. The peripheral pulses are usually normal, though sometimes jerky because of the predominant ejection of blood in early, rather than late, systole. The jugular venous pulse is normally not elevated. On palpation of the heart, left rather than right hypertrophy is usually discovered. On auscultation, the first and second heart sounds are usually normal, except in the relatively rare case of pulmonary hypertension. There is a blowing pan-systolic murmur at the apex. The pan-systolic murmur of ventricular septal defect is much rougher, is maximal at the left sternal border, and does not radiate to the axilla. If mitral regurgitation is more than mild to moderate, an apical third heart sound will be heard, followed in severe cases by a diastolic flow murmur. This diastolic murmur, particularly if it is accompanied by a third sound, does not necessarily indicate stenosis. When congenital mitral anomalies are associated with other cardiac defects, the physical signs are usually dominated by the other lesions. In particular, an imperforate mitral valve generates no direct physical signs, though evidence of pulmonary hypertension is almost invariable. The main clue to the presence of mitral stenosis in association with other defects is an inappropriately prominent mid-diastolic murmur. A typical example would be that of a 6-month-old child who, in earlier life, had typical signs of ventricular septal defect and yet who now has all the signs of Eisenmenger's syndrome except an unexpected loud mid-diastolic murmur, often with presystolic accentuation. Care has to be taken with many children with aortic coarctation, and a few with discrete subaortic stenosis. Such patients may have short apical mid-diastolic murmurs, which, for reasons that are not obvious, disappear after resection of the obstruction.

INVESTIGATIONS

Electrocardiography

Sinus rhythm is the rule in children, though first-degree heart block is common, particularly when the left atrium is greatly enlarged. Left atrial hypertrophy occurs in about nine-tenths of patients, and right atrial hypertrophy is the rule in patients with pulmonary hypertension. In mitral stenosis, the mean frontal QRS axis is usually normal, or to the right and inferior, whereas it is generally normal in mitral incompetence. The pattern of ventricular hypertrophy reflects the underlying haemodynamics. Consequently, patients with mitral stenosis tend to have right ventricular hypertrophy, while those with mitral incompetence have left ventricular hypertrophy. All of these findings are modified by associated abnormalities. In patients with the physical signs of mitral regurgitation, the electrocardiogram provides important clues to the presence of atrioventricular septal defects with common atrioventricular junction, when there is a superior counter-clockwise QRS loop, and discordant atrioventricular connections, characterised by Q waves in the right and inferior precordial leads. Mitral regurgitation

secondary to anomalous origin of the left coronary artery from the pulmonary trunk is suggested by a pattern of anterolateral infarction.

Chest Radiography

Whatever the nature of the mitral abnormality, cardiac enlargement tends to be considerable. Splaying of the bronchuses by the enlarged left atrium is particularly prominent. Infants with imperforate mitral valve, or severe mitral stenosis, very occasionally show the ground-glass appearance of pulmonary oedema. More commonly, left atrial hypertension is manifested in older children by Kerley B lines and diversion of blood to the upper lobes. In infants, the pulmonary trunk and left atrial appendage do not form discrete bulges on the upper left cardiac border, which is consequently straighter than normal. In older children, prominence of the left atrial appendage is the rule and, in patients with pulmonary hypertension, the pulmonary trunk is prominent. These appearances may be profoundly modified by associated abnormalities. If the ascending aorta is seen on the left upper cardiac border and the patient has clinical features of mitral incompetence, then congenitally corrected transposition with tricuspid rather than mitral incompetence is the most likely diagnosis.

Echocardiography

M-mode echocardiography provides non-specific evidence as to enlargement of the left ventricle, left atrium, and right ventricle. It is unhelpful in diagnosing mitral incompetence. A number of features are suggestive of mitral stenosis, but none of them is invariably present. These include anterior movement of the mural leaflet in diastole, a prolonged time to reach one-fifth of the peak rate in change of left ventricular dimensions, and a reduced peak rate of these changes in dimension.²⁹ A flattening of the E-F slope is again suggestive, but difficult to recognise in infants with tachycardia (Fig. 35-19). The time from closure of the aortic to opening of the mitral valve, and from left ventricular minimum dimension to mitral opening, have proved unhelpful as indicators of congenital mitral stenosis,³⁰ though they are useful in assessment of acquired mitral valvar disease.

Figure 35-19 This M-mode echocardiogram is from a patient with mitral valvar stenosis. Note the prolonged E-F slope, and the anterior motion of the mural leaflet.

Cross Sectional Echocardiography

The advent of this modality made a major difference to the non-invasive understanding of pathology.²⁸ Assessment usually consists of short-axis scans from the apex of the left ventricle to the base, carried out from both subcostal and precordial windows. In such scans, the papillary muscles normally appear at 3 and 8 o'clock in the parasternal short-axis view.²⁹ In the parachute valve, the two muscles are usually fused into one. The alternative arrangement, with hypoplasia or absence of one papillary muscle, may also be observed, particularly in patients with associated coarctation.²⁹ The paired papillary muscles are frequently closer together (Fig. 35-20) in cases with coarctation of the aorta.³¹ As the beam is moved towards the base, so the mitral orifice appears. This is normally symmetrical but is frequently eccentric in patients with congenital mitral stenosis; consequently, standard cuts give little idea of the severity of stenosis. This view is also of value for recognising the anomalous mitral arcade.³² The most striking and important abnormality recognised in these short-axis sections is the isolated cleft of the aortic, or anterior, leaflet. This appears as a splitting of the leaflet into two during diastole. The cleft points to the left ventricular outflow tract, not the septum,³³ and is seen in normal short-axis planes,³⁴ not the horizontal precordial plane, which best demonstrates the zone of apposition between the left ventricular components of the bridging leaflets in atrioventricular septal defect with common atrioventricular junction (Figs. 35-21 and 35-22). When it is the mitral valve that is involved, the orientation of the papillary muscles is also normal in the majority of cases.³⁵ Cordal attachments from the edges of the cleft aortic leaflet are frequently observed. In hearts with discordant ventriculo-arterial connections, or double outlet right ventricle with subpulmonary ventricular septal defect,³⁶ particularly in the presence of a straddling mitral valve (Fig. 35-23), we have observed that the cleft appears to be more asymmetrical, pointing towards the anterolateral aspect of the left ventricle. This, in turn, is often associated

Figure 35-20 This short-axis echocardiographic view shows a patient with a dominant anterolateral papillary muscle (arrow). Note that most of the mitral valve is inserted into this dominant muscle. LV, left ventricle; RV, right ventricle.

with medial rotation of the supero-posterior papillary muscle. It has been questioned on embryological premises whether this represents a true cleft in the mitral valve as opposed to a commissure.³⁷ In functional terms, however, the space is not a usual zone of apposition between valvar leaflets, and it requires closure at surgery.

The short-axis view also provides an excellent means for identifying dual orifices in the mitral valve (Fig. 35-24), particularly when each orifice is supported by its own papillary muscle.^{38,39} Parasternal long-axis sections permit further assessment of texture and mobility of the leaflets. They frequently demonstrate crowding of the subvalvar apparatus, with difficulty in differentiating between the leaflet and the tension apparatus to which it is fused. This is particularly valuable for detecting a so-called supramitral ring, which is usually associated with both valvar and subvalvar pathology (Fig. 35-25). As has been emphasised, the ring is usually related intimately to the valvar leaflets.¹² The ring,

Figure 35-21 The diagram shows the difference between an isolated cleft in the aortic leaflet of the mitral valve, and the zone of apposition between the left ventricular components of the bridging leaflets (BL) seen in atrioventricular septal defect with common atrioventricular junction. Note that the isolated cleft of the aortic leaflet points to the left ventricular outflow tract, while the zone of apposition between the bridging leaflets is directed towards the ventricular septum.

Figure 35-22 This precordial short-axis view demonstrates an isolated cleft in the aortic leaflet of the otherwise normal mitral valve. Note the thickened edges of the cleft. LA, left atrium; LVOT, left ventricular outflow tract; RV, right ventricle.

Figure 35-24 The precordial short-axis view demonstrates a double orifice in the mitral valve. Note that one orifice is smaller than its counterpart. OR1, orifice 1; OR2, orifice 2; RV, right ventricle.

Figure 35-23 The parasternal long-axis view demonstrates straddling of the aortic leaflet of the mitral valve (*arrow*). Note that it attaches to the right side of the upper margin of the ventricular septum. LA, left atrium; LV, left ventricle; RV, right ventricle.

Figure 35-25 This transoesophageal echocardiogram shows a so-called supramitral ring (*arrow*), with attachments to the aortic leaflet of the valve. Note that the fibrous ring is attached within the funnel of the valvar leaflets. Also note the abnormal thickening of the valvar leaflets. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

which starts at the annulus, extends downwards onto the valve leaflets, such that at first glance the echocardiographer has the impression that it is an intravalvar structure.

Normal values have been published for mitral annular dimensions as seen in parasternal long-axis and apical four-chamber views.⁴⁰ In the great majority of patients with congenital mitral stenosis, these values are normal. Occasionally, particularly in the presence of a ventricular septal defect, annular hypoplasia can be the main component of the mitral stenosis. Four-chamber sections, either from the apical or subcostal approach, complete the morphological picture, with the former providing the best location for Doppler assessment of any valvar gradient. As in the parasternal long-axis

view, the valve appears to be thickened, with evidence of doming during the cardiac cycle (Fig. 35-26). The presence of a supramitral ring is also appreciated in this position. This position is also suitable for diagnosing the rare finding of Ebstein's malformation of the mitral valve, and for assessing left atrial size. In this condition, the aortic leaflet of the mitral valve originates normally with respect to the tricuspid valve, but the mural leaflet is displaced downwards.⁶ Mitral regurgitation secondary to myocardial dysfunction is suggested by poor myocardial contractility and/or dyskinesia.

It is essential to demonstrate origin of the left coronary artery from the aortic root in all patients with the clinical picture of pure mitral regurgitation, bearing in mind

Figure 35-26 The four-chamber view shows dysplastic mitral valvar stenosis. Note the thickened leaflets, shortened cords, and an associated so-called supramitral ring. AO, aorta; LA, left atrium; LV, left ventricle, RV, right ventricle.

that, in patients with a pericardial effusion, the transverse sinus of the pericardium may be mistaken for the left coronary artery by the inexperienced observer. If not diligently sought, anomalous origin or atresia of the left coronary artery may well be missed. With the advent of colour flow Doppler, in conjunction with a measurement of the right coronary artery,^{41,42} it is now rare to miss the diagnosis. Imperforate mitral valve may be recognised as a thin, sometimes mobile, membrane between the left atrium and left ventricle, which can usually, but not invariably, be distinguished from the thick wedge produced by the atrioventricular groove when the left atrioventricular connection is absent. In other cases, the mitral valvar regurgitation can be caused by dysplastic leaflets that are relatively immobile, thus preventing full coaptation during systole (Fig. 35-27). From personal experience, the mural leaflet seems to be involved more frequently in this process.¹¹

Figure 35-27 The cross sectional image, and colour Doppler display, in a patient with dysplastic mitral valvar regurgitation. There is poor coaptation of the leaflets (arrow), with a large central jet of regurgitation. LA, left atrium; LV, left ventricle.

Figure 35-28 The continuous wave tracing shows the flows across a stenotic mitral valve. Using this trace, it is possible to calculate the mean gradient across the valve (see Chapter 18A).

Pulsed and Continuous Wave Doppler Echocardiography

Doppler echocardiography has had a major impact on the evaluation of mitral valvar disease, in the areas of both stenosis and regurgitation. With mitral valvar stenosis, a turbulent inflow jet is seen, both by pulsed and continuous wave Doppler. The latter modality can be used to calculate the gradient across the valve, and also its area. In adults and older patients, the pressure half-time provides an accurate assessment of area, independent of cardiac output. This same technique can be applied to children, although absolute areas calculated in this way are of little value because of the wide variation in body surface area.⁴³ Mean gradients across the valve, as assessed using colour flow images, have traditionally been used in assessment of congenitally malformed hearts (Fig. 35-28), despite the limitation of their dependency on cardiac output.⁴³ In our laboratory, we use a combination of pressure half-time, mean mitral gradient, and left atrial size to assess the severity of congenital mitral valvar stenosis. This, in conjunction with an assessment of pulmonary arterial pressure, either resulting from tricuspid regurgitation or pulmonary insufficiency, completes the haemodynamic evaluation.

While pulsed Doppler flow mapping has fallen from grace in assessing the severity of mitral regurgitation, it still plays a small semiquantitative role through the use of pulmonary venous sampling. In general, reversed systolic flow is seen in hearts with more severe regurgitation.⁴⁴ A quantitative measurement of regurgitant volume and fraction can be obtained using pulsed Doppler techniques. This is achieved by calculating the difference between forward stroke volume through the aorta and that measured through the mitral valve, the latter consisting of normal pulmonary venous return plus the regurgitant volume.⁴⁵

The contribution of colour flow Doppler in this lesion is twofold. First, it excludes or establishes associated regurgitation and, second, it pinpoints the site of obstruction and the pattern of flow through the valve (Fig. 35-29). In patients with an associated supramitral ring, the variance starts just above the annulus. In the other forms, it starts below the level of the annulus. This technique also provides valuable clues about the site of exit of the blood. In a parachute valve, for example, there appears to be a conical jet of blood, whereas in those with two papillary muscles, the jet is more dispersed. Assessment of mitral valvar regurgitation is well suited to the technology of colour flow Doppler. This

Figure 35-29 The colour flow tracing comes from the same patient as shown in Figure 35-28. Note that there is aliasing just beyond the annulus, with variance distal to that. LA, left atrium; RA, right atrium; RV, right ventricle.

technique permits an accurate assessment of the site of the regurgitant jet, for example from the edges of a cleft mitral valve or at the site of prolapse in those with floppy leaflets. It also provides information regarding the direction of the jet, along with the extent to which the velocity signal can be observed in the left atrium. One of the major problems, however, is that mapping of flow provides only a semiquantitative assessment of the severity of the regurgitation, as the echocardiographer measures velocity not volume. Despite this limitation, a reasonably reliable assessment of severity is possible, particularly if more than one plane is used. Limitations relate to depth, position of the jet in relationship to the atrial wall, gain settings, driving pressure, and transmitted frequency.^{46,47} Similarly, in large populations of apparently normal subjects, physiological mitral regurgitation is encountered in up to around two-fifths of individuals.⁴⁸

More recently, attempts have been made to assess the volume of flow by using other techniques, such as calculations of the proximal isovelocity surface area, or PISA, by cross sectional echocardiography (Fig. 35-30), and the width of the jet.^{49–52} These are, potentially, the key to an accurate assessment of volume of flow, which can then be related to changes in left ventricular dimension. The problem with calculation of the proximal isovelocity surface area is that it does not account for varying shapes of the regurgitant orifice. A recent study comparing use of this feature in the calculation of regurgitant volume, to that measured by real-time three-dimensional echocardiography, showed that the former method significantly underestimated the true volume.⁵²

The problem, at present, is that it is not clear whether an increase in the size of a ventricle represents a deterioration in ventricular function, or just an alteration to accommodate an increase in regurgitant volume.⁵³ As a result of problems in calculating absolute regurgitant volumes reproducibly by Doppler echocardiography, the role of this method in children has still to be established. It is

Figure 35-30 The anatomy of a regurgitant jet as revealed by colour Doppler interrogation. The red arrow represents the aliasing velocities, the so-called PISA, while the black arrow shows the regurgitant jet in the left atrium. The upper white arrow in the left hand picture is pointing at the so-called vena contracta, while the lower white arrow shows the PISA. LA, left atrium; LV, left ventricle.

probably safer to extrapolate from data obtained in adults using an indexed end-systolic diameter of greater than 4.5 cm, or an ejection fraction by volumetric assessment of less than 60%, as echocardiographic indications of the need for valvar surgery.^{54,55}

The more recent advent of transoesophageal echocardiography has provided an additional tool for the evaluation of the congenitally abnormal mitral valve. Fortunately, apart from the older child or obese patient, this technique is unnecessary in most children. It is also apparent that transoesophageal colour flow mapping appears to be more sensitive than transthoracic assessment. Systematic overestimation of the severity of regurgitation is found when it is compared with standard transthoracic assessment.^{56,57} Despite this difference, both techniques provide a good correlation with angiography and surgery.^{57,58}

Three-Dimensional Echocardiography

Until recently, adequate three-dimensional echocardiographic images of the mitral valve were possible only using the transoesophageal rotational system, which could be used only in children weighing more than 13 to 14 kg. The technique also usually required intubation, which resulted in minimal practical application for children. Likewise, due to the rotational nature of the collection of data, little information was typically obtained regarding the subvalvar apparatus. With the recent advent of the matrix array real-time three-dimensional echocardiographic system, a whole new world has opened up to the echocardiographer. More recently, a higher frequency matrix array transthoracic probe has become available which permits imaging in neonates and infants. Importantly, this permits the echocardiographer to image not only the leaflets, but also the subvalvar apparatus (Figs. 35-31 and 35-32). The data can be displayed so as to provide a surgical view, thus permitting the surgeon finally to understand the presented echocardiographic images. Another important view is that seen from the left ventricular aspect. This permits a more detailed assessment of the zones of apposition between the edges of the leaflets. The leaflets billow naturally in systole, which

Figure 35-31 The three-dimensional echocardiographic image shows a dysplastic mitral valve with associated stenosis. Note the thickened aortic and mural leaflets. There is some tethering of the mural leaflet, seen near the end of the zone of apposition between the leaflets. AO, aorta; AOL, aortic leaflet; ML, mural leaflet; RV, right ventricle.

Figure 35-32 This three-dimensional echocardiographic image shows a cleft (arrow) in the aortic leaflet of the mitral valve, as seen from the left ventricle. The cleft points towards the left ventricular outflow tract. LVOT, left ventricular outflow tract; ML, mural leaflet.

makes assessment of their zone of apposition difficult in some cases when viewed in surgical fashion. This can, in part, be overcome by cropping just below the annulus of the mitral valve when seen in this view. It is also possible to combine real-time three-dimensional colour Doppler imaging, which helps provide an improved understanding

of regurgitant jets. This technique also provides details regarding regurgitation through the zone of apposition, which has previously been difficult to demonstrate using standard cross sectional imaging. There is already data emerging to show the additional benefit of three-dimensional echocardiography in adults with mitral valvar pathology.^{59–62} At present, there is some data acquired in children showing the benefit of the technique in evaluating left atrioventricular valves, particularly with regards to abnormalities of the zones of apposition between the leaflets.^{63,64}

Magnetic Resonance Imaging

This technique is currently finding its role in the routine investigation of the child with a congenitally malformed heart. So far, its strengths have revolved around the evaluation of the extracardiac anatomy, in particular the aortic arch and pulmonary arteries, where detailed structural information is available. The technique is equally suited to the evaluation of intracardiac structures, both static and dynamic. The mitral valve can be imaged in several planes, along with its supporting papillary muscles. Few data is available at present with regards to detailed anatomical descriptions of congenital anomalies. While this would be interesting, it is probably in the area of functional assessment that the technique holds the greatest promise. The ability to assess mass and volume with a high degree of accuracy, in conjunction with the determination of regurgitant volumes, is of great potential for the evaluation of the chronically regurgitant mitral valve. This is achieved by phase shift velocity mapping, which permits the assessment of mean velocities. These can then be integrated over time and, when multiplied by area, yield volume flow. Using this technique, a very good correlation has been found between measured and calculated regurgitant volumes, with a correlation coefficient of 0.99.⁶⁵ As well, it provides more reliable data with regards to mitral annular diameter when compared to cross sectional echocardiography.⁶⁵ Of note, with the introduction of three-dimensional echocardiography, this limitation of the cross sectional modality should be overcome.

Cardiac Catheterisation

The final arbiter of mitral obstruction is demonstration of a difference in diastolic pressures between the left atrium and ventricle. Murphy's law dictates that, when you most need to know the left atrial pressure, it is most difficult to obtain. The high left atrial pressure seems to seal the valvar mechanism of the oval foramen with remarkable effectiveness. Entry to the left atrium from the right, therefore, often demands trans-septal puncture. While this technique is remarkably safe, particularly in the hands of experts who practise it constantly, it is not to be recommended to the occasional operator. Retrograde passage of the catheter through the mitral valve is an alternative but is more difficult if the valve is stenotic. Before any of these techniques are used, efforts should be made to obtain a satisfactory pulmonary capillary wedge pressure simultaneous with the left ventricular pressure. The wedge pressure can be regarded as a reliable reflection of left atrial pressure if the wave form is undamped, fully saturated blood can be aspirated through the catheter and repeated

measurements in different sites give the same pressure. Routine measurement of wedge pressures during cardiac catheterisation goes a long way towards detecting otherwise masked mitral stenosis. The documentation of a pressure gradient between the pulmonary capillary wedge pressure and the left ventricular diastolic pressure only proves the existence of mitral stenosis or supra-valvar ring if the pulmonary veins are normally connected to the left atrium and there is no partition, tumour or thrombus within it. All of these can be excluded by cross sectional echocardiography.

Angiocardiography

In general, angiocardiography has been relegated to the history books for the evaluation of mitral valve pathology and function. It is rarely used in this era to diagnose lesions responsible for mitral valve regurgitation or stenosis, nor is it utilised to quantify the severity of a regurgitant valve. Although certain pathological entities can be determined by this technique, these represent an indirect evaluation, rather than the true pathology as seen by either two- or three-dimensional echocardiography.

DIFFERENTIAL DIAGNOSIS

As already emphasised, the main problem lies in recognising that a mitral valvar anomaly is present when associated defects dominate the clinical picture. Careful clinical examination and echocardiography, coupled with a high index of suspicion in patients with other left-sided obstructive lesions, provides the best means of making the diagnosis. In secondary mitral regurgitation, left ventricular dysfunction usually dominates the clinical picture, whereas left ventricular function is usually normal in primary regurgitation. The possibility of silent mitral stenosis always haunts the clinician confronted with the patient with apparently severe and irreversible pulmonary vascular disease. Currently cross sectional, three-dimensional echocardiography, and Doppler examination can rule out significant obstruction in all cases, making catheterisation unnecessary for diagnostic purposes in patients where high-quality non-invasive investigation is possible.

COURSE AND PROGNOSIS

In this current era, patients with severe obstruction to left ventricular inflow, and relative left ventricular hypoplasia, are frequently managed along protocols involving an initial Norwood procedure, followed by a construction of cavopulmonary shunt prior to conversion to the Fontan circulation. Many of these are diagnosed prenatally, with the neonates in consequence being in a more stable condition, usually because of infusion of prostaglandins. Mitral stenosis with an adequate size left ventricle has a slightly better, but still poor, prognosis. In one series,²⁶ actuarial survival was shown to be 40% at 10 years of age when patients were treated medically, and 56% at the same age for surgically treated patients. At the age of 18 years, survival was 18% in both groups. Although the prognosis has improved in the current era, it still carries a higher mortality and morbidity than those presenting at a later age. Mitral incompetence has the best prognosis. Even when associated with

coarctation, most patients survive childhood. The degree of mitral regurgitation may remain static, or even decrease once the coarctation is resected. Prolonged and significant mitral regurgitation will eventually depress left ventricular function, though it is unclear whether it does so at a similar rate as in adults.

MANAGEMENT

Medical Management and Timing of Intervention

For patients with congenital stenosis, medical management is frequently dictated by the nature and severity of the associated lesions. In those patients where the valvar lesion is isolated, treatment with diuretics may buy some time. Although surgical repair is possible, the long-term results are disappointing. Unfortunately, pulmonary hypertension is frequently encountered in these patients, thus forcing the hand of the cardiologist and surgeon. Until recently, surgery was the only option, but in both adults and children, angioplasty has now become the treatment of choice for those with rheumatic valvar disease, with acceptable results published in the short term.^{66,67} There is little data for balloon angioplasty performed in the setting of congenital mitral valvar stenosis, albeit that encouraging results have now been reported from a single center with many years experience, the results being comparable to those provided by surgical intervention.⁶⁷ In this series, those with a supramitral ring, prior mitral valvar regurgitation, and being younger at the time of intervention, all suffered a poorer outcome after dilation. For those who did not have these adverse risk factors, there was a good initial reduction in gradient, albeit a high risk of recurrent stenosis, and with over a quarter developing significant valvar regurgitation. Regurgitation is generally managed medically until there is evidence of clinical symptoms that are not improved by standard therapeutic regimens combined with a trial of afterload reduction. With the introduction of inhibitors of angiotensin converting enzyme, which reduce the afterload on the left ventricle, morbidity and mortality have both been shown to improve in adults with left ventricular dysfunction.^{68,69} Thus far, however, no studies have demonstrated that such treatment in isolation prolongs the time from diagnosis to eventual repair, or replacement in cases where regurgitation is the primary lesion, and is not secondary to left ventricular dysfunction. Indeed, in one investigation using an animal model of chronic mitral regurgitation, inhibition of angiotensin converting enzyme decreased the end-diastolic pressure in the left ventricle, along with the pulmonary capillary wedge pressure, but did not increase the forward stroke volume, nor the contractility.⁷⁰ The addition of β -blockade to the inhibition of the angiotensin converting enzyme had similar affects, although β -blockade also increased forward stroke volume and contractility.

Surgical Management

Patients with severe mitral valvar stenosis who present in the neonatal period, and frequently have some degree of left ventricular hypoplasia and aortic valvar stenosis, now tend to be managed by following the Norwood sequence of operations. This includes creating an aortopulmonary anastomosis, performing an open atrial septectomy, and constructing a shunt from the aorta to the pulmonary

arteries, either centrally or peripherally, or more recently placing a conduit from the right ventricle to the pulmonary arteries. It is also possible to perform the so-called hybrid procedure, which involves banding of the right and left pulmonary arteries, stenting the persistently patent arterial duct, and in some cases, stenting the interatrial communication. The hybrid procedure, when performed, is a prelude to construction of a cavopulmonary shunt and aortic reconstruction at 4 to 5 months of age.

Outside the neonatal period, if balloon valvoplasty is not available, the best option is to attempt to repair the valve, as valvar replacement in children is still fraught with problems. The presence of intractable heart failure, severe pulmonary hypertension, or pulmonary oedema, means that the need for operation in infancy or early childhood is forced upon the management team. In contrast, in congenital mitral incompetence, the generally good prognosis with medical management means that operation can usually be postponed for as long as is possible. The exception to this conservative approach is that for the isolated cleft of the aortic, or anterior, leaflet of the valve, where the results of repair are so good as to justify surgery at any age if there is significant cardiomegaly.⁷¹

Reconstructive surgery currently has acceptable results with regards to mortality and morbidity over the medium term. Both a younger age at presentation and the association with additional intracardiac lesions are associated with a poorer outcome. In general, survival over the medium term is close to 90%, with a freedom from reoperation of approximately 76% over the variously reported periods of follow-up.^{72–74} There are multiple surgical techniques that are tailored to the specific pathology at the levels of the annulus, leaflets, and supporting tension apparatus. Frequently, due to the complex nature of the valvar pathology, one or more of these has to be applied to an individual patient. For regurgitant valves, it is possible to perform annuloplasty, or insert mitral rings, with the latter currently being designed so as to fit the normal saddle-shape of the mitral valvar annulus. For those with dysplastic leaflets, augmentation has been employed with some success. Occasionally, it is necessary to place a stitch between the leaflets so as to create double orifices within the valve. For stenotic lesions, it is possible to resect supra-mitral ring, split the papillary muscles in those with the parachute malformation, enlarge the zone of apposition between the leaflets, or resect accessory valvar tissue.⁷⁵ It is also possible to shorten or transfer the tendinous cords, as well as insert synthetic cords.

Replacement of the valve is considered only after all other surgical options have been exhausted. Even in this current era, the results of valvar replacement are still somewhat disappointing, particularly in the very young child. The initial experience gained with insertion of homograft valves was disappointing, with reoperation needed in two-fifths at 5 years, and three-fifths by 7 years. As a result, this technique is rarely used in this current era. Mechanical valves are the treatment of choice, with the valves inserted usually being bileaflet and having a low profile. From several series that followed patients from 10 to 15 years, overall survival was in the mid-1960s, with freedom from the need to insert a second valve varying between 54% and 66%.^{76–78} With improved management of anticoagulation, the incidences of thrombosis and infection are low,

occurring in less than one-tenth. It is the need for valvar replacement, and the size of the initial prosthesis, that stratifies the patients. In many younger patients, where stenosis is the predominant lesion, there is associated annular hypoplasia that limits the size of the prosthesis which can be inserted during the initial operation. Indeed, in some cases the annulus is deemed too small, and the prosthesis has to be positioned in the supra-annular position. Although there has been some limited experience with this approach, it is not without complications.⁷⁹ To overcome this problem, some groups have used a pulmonary autograft in the so-called Ross-2 procedure. The pulmonary valve removed from the patient is sewn into a Dacron tube, which is then inserted into the mitral annulus. Although experience is limited with this technique, the initial results seem encouraging, with a low mortality, albeit that as yet there is no data over the long term.⁸⁰

MITRAL VALVAR PROLAPSE

Incidence

Suggestions were made, based on M-mode evaluation, that prolapse could afflict up to one-third of the otherwise normal population. When cross sectional echocardiography was introduced, the incidence was still high, despite its improved spatial resolution. This was due, in part, to a lack of understanding of the anatomy of the mitral valvar annulus. This was initially believed to be planar, and hence the diagnosis of prolapse was made using both long-axis and four-chamber views. The advent of three-dimensional echocardiography has pointed to the incorrectness of these approaches, since the normal valvar annulus has high and low points, appearing like a saddle.⁸¹ It is the anterior and posterior aspects that represent the high points, while the medial and lateral parts are the low points. Taking into account this morphology, prolapse of the leaflets should only be consistently diagnosed when using the parasternal long-axis view. Using this criterion, a report from the Framingham study demonstrated an incidence of 2.4%.⁸² Such improved accuracy of diagnosis will have a profound effect on future genetic studies.

The diagnosis is rarely made in young children and indeed is exceptionally rare in neonates outside those patients having Marfan's syndrome and presenting in the neonatal period. With an improved understanding of the structure of the mitral valve, and its potential genetic implications, the lack of diagnosis in childhood points to the need for many years of stress on a potentially abnormal valve before the leaflets begin to prolapse.

Genetics

Non-syndromal prolapse is probably an autosomal dominant disorder, with variable penetrance, as there is clinical heterogeneity in families. It is well recognised that prolapsing leaflets of the mitral valve are found in patients with Marfan's syndrome, Ehlers-Danlos syndrome, osteogenesis imperfecta, dominant cutis laxa, and pseudoxanthoma elasticum. Prior studies had failed to link the familial and non-syndromal disease with fibrillar or other collagen genes. The recent ability to understand the three-dimensional nature of the mitral valve has provided greater diagnostic specificity, and this has provided an improved understanding of the

genetics of the nonsyndromal variant. Based on this new understanding, myxomatous prolapse has been linked to chromosome 16 in some families with an autosomal dominant form, while in others linkages have been found with chromosome 11p15.4 and 13q31.3–q32.1. Some of the studies have identified a prodromal form, with no true prolapse, but rather with anterior shifted of the zone of coaptation, indicating elongation of the mural leaflet. Others have studied an X-linked valvar dystrophy with mutations of so-called filament A. Overall, therefore, the genetic background to mitral valvar prolapse may be similar to that found for hypertrophic cardiomyopathy, with multiple genetic abnormalities responsible for a common phenotype.²⁵

That prolapse is due to a structural abnormality of the proteins has little support outside the mutations of collagen found in Ehlers-Danlos syndrome. The picture appears to be more complex than a simple mutation in fibrillin. Indeed, recent work has demonstrated that the picture is more complex. Mice with a fibrillin-1 mutation can be rescued by perinatal administration of neutralising antibodies to TGF β , a growth factor that stimulates activity and matrix formation by the valvar interstitial cells. Fibrillin is, therefore, an important regulator of the interplay between growth factors made by interstitial cells and the cells themselves. The current theory is that fibrillin stabilises the TGF β complex so that a mutation results in overexpression of TGF β .

Presentation, Symptomatology, and Pathophysiology

An understanding that prolapse of the leaflets of the mitral valve represents an increase in area and length of the tissues that happens over many decades helps to explain why the lesion is uncommon in childhood and adolescence, outside of those patients with co-existing disease of the connective tissues. The leaflets billow back and cross the line of coaptation, which normally is in close proximity to the plane of the superior part of the mitral annulus. Eventually, regurgitation ensues in some patients, which progresses to resultant heart failure, and its associated symptoms. In children, therefore, the majority of patients have no symptoms at all. They present with murmurs found on routine examination, usually in late adolescence or adulthood. Early presentation should raise the suspicion of Marfan's syndrome. The intensity of the murmur is critically dependent on posture. A large minority of patients have other symptoms. The most common is chest pain, usually unrelated to activity, that is ill-defined, located to the praecordial area, is sharp and fleeting, or more prolonged. Other symptoms include dyspnoea, fatigue, light-headedness, and palpitations.

Physical Signs

It is frequent to find associated skeletal abnormalities, such as a flat chest, a straight back, or a pigeon chest. Peripheral arterial and venous pulses are normal. Palpation of the heart is usually normal, unless a honk is present. This is usually accompanied by a thrill. Careful palpation with the patient lying in left lateral position may permit detection of mid-systolic retraction. Auscultation at the apex reveals a mid-systolic click, which may be multiple; a late systolic murmur; or both.

The murmur must be heard to reach the second heart sound, if necessary by inching the stethoscope from the

Figure 35-33 The phonocardiogram shows a mid systolic click and late systolic murmur in a patient with a floppy mitral valve. CL, click; LSM, late systolic murmur.

apex to the base. Clicks are sometimes heard only with the patient upright, or lying in the left lateral position (Fig. 35-33). As long as the murmur remains late systolic, the heart sounds can be normal. When the murmur is holosystolic, then a loud first heart sound indicates early prolapse. A soft first heart sound indicates flail leaflets. Manoeuvres that decrease left ventricular end-diastolic volume, or increase the rate of left ventricular contraction, such as sitting or standing from the supine position, the strain phase of a Valsalva manoeuvre, tachycardia, or administration of vasodilators such as amyl nitrate, all move the click and murmur closer to the first heart sound. Squatting, the release phase of the Valsalva manoeuvre, bradycardia, and administration of vasoconstrictors, in contrast, all move the click and murmur towards the second heart sound, and often make the murmur become fainter or disappear. Pregnancy also may cause disappearance of the murmur.

With prolonged follow-up, the murmur does become pan-systolic in some adults. This finding is rare in children unless they have Marfan's syndrome. An early diastolic sound or, less often, an early diastolic murmur, is occasionally heard or recorded by phonocardiography. This has been ascribed to recoaptation of the prolapsing leaflets, but could also be caused by prolapse of the leaflets of the aortic valve.

Investigations

Chest Radiography

Chest radiography usually gives normal results, apart from the skeletal abnormalities already noted. If mitral valvar regurgitation is severe, there will be an increase in the cardiothoracic ratio and the size of the left atrium.

Electrocardiography

About one-fifth of children with the auscultatory syndrome have inverted T waves in leads II, III, and aVF and rather less commonly in leads V₅ and V₆. These abnormalities may not be constant. Prolongation of the Q–Tc interval occurs in up to one-sixth of all patients.^{83,84} Although brief runs of ventricular and supraventricular tachycardia have been described, many of these findings are also seen in normal individuals.⁸⁵

Echocardiography

When the cross sectional echocardiographic appearances of prolapsing leaflets are appreciated, it becomes easier to understand how pseudo-prolapse may be produced using M-mode interrogation. Cross sectional echocardiography, and particularly the three-dimensional format, enhances the diagnosis of prolapse by enhancing the spatial configuration of the valvar leaflets.⁸⁶ During diastole, the leaflets of the normal valve lie widely open and are more-or-less parallel, as seen in parasternal long-axis sections. With the onset of systole, the two leaflets, moving in opposite directions, coapt to give a funnel-shaped appearance. As systole continues, the line of coaptation moves anteriorly and lags behind the aortic root. The entire valvar apparatus then moves anteriorly and inferiorly. Both leaflets frequently arch slightly towards each other and become more horizontal, but no part of the leaflets appears above the plane of the atrioventricular junction. In prolapsing valves, the mural or, less often, the aortic leaflet, or sometimes both, arch towards each other to an excessive degree, passing above the plane of the atrioventricular junction into the left atrium. The line of coaptation between the leaflets is displaced superiorly and posteriorly. M-mode criteria for the floppy valve syndrome are mid-systolic buckling and pan-systole hammocking. Despite these observations, there was a tremendous over-diagnosis of mitral valve prolapse by M-mode echocardiography, so much so that it is rarely used in this current era.

Cross sectional echocardiography has provided improved spatial resolution, but initially, as already explained, was just as guilty in misleading the clinician and echocardiographer. It is the observation that the valvar annulus is not perfectly circular, but rather possesses a saddle-shape, with one dimension being in a different plane to the other,^{87,88} which provides an explanation for the discrepancy between findings obtained using the parasternal long-axis and four-chamber views. It has been suggested,⁸⁶ therefore, that fairly reliable signs of mitral valvar prolapse include late systolic bulging as seen on M-mode tracings, displacement of the leaflets into the left atrium by more than 2 mm as seen in the parasternal long-axis view, along with thickening of the leaflets (Fig. 35-34). Regurgitation in the setting of prolapsing leaflets is best assessed by colour flow Doppler interrogation. Care must be taken if attempts are made to quantify the severity by using the phenomenon of the proximal isovelocity surface area, since the amount of regurgitation is not constant throughout systole.⁸⁹

Transoesophageal multi-plane echocardiography is useful in identify the specific components of the leaflets that are prolapsing. At 20 degrees interrogation, it is the medial component of the aortic leaflet, along with the lateral scallop of the mural leaflet. At 60 degrees, it is the medial and lateral scallops of the mural leaflet, along with the middle part of the aortic leaflet. Interrogation at 90 degrees shows the medial scallop of the mural leaflet, along with the lateral part of the aortic leaflet, while using scans from 120 to 160 degrees shows the middle parts of both leaflets.⁵⁸ Even though this has been helpful to the cardiologist and surgeon, such interrogation is now being replaced by three-dimensional echocardiography to aid in the diagnosis and surgical planning of patients with prolapse. Indeed, views showing the structure of the valve as seen by the surgeon in the operating room can be obtained from either the transthoracic approach using either real-time three-dimensional

Figure 35-34 The cross sectional parasternal long-axis view in a patient with prolapsing mitral valve. Although the prolapse is seen (arrow) it is difficult to pinpoint which component of the aortic leaflet is involved. LA, left atrium; LV, left ventricle.

echocardiography or, until recently by transoesophageal echocardiography using a rotational device. There is good evidence emerging that the three-dimensional technique is superior to either transthoracic and transoesophageal cross sectional echocardiography with regards to identification of specific pathology of different parts of the leaflets, as well as abnormalities along their zone of apposition (Fig. 35-35). As this book is being prepared for publication, the transoesophageal real-time three-dimensional echocardiographic

Figure 35-35 The prolapsing valve seen in Figure 35-34 as revealed by three-dimensional echocardiography, prepared so as to show the valve as seen by the surgeon in the operating room. Note that the prolapse involves the lateral part of the aortic leaflet of the mitral valve. AO, aortic valve; RV, right ventricle. A1, A2, portions of the aortic leaflet of the mitral valve facing the scallops of the mural leaflet usually described as P1 and P2.

probe is about to be released, which should further enhance the role of three-dimensional echocardiography.

Cardiac Catheterisation and Angiocardiography

In this current era, cardiac catheterisation, and angiography, is not used to make the diagnosis of, nor to assess, a patient with prolapsing leaflets of the mitral valve.

Course and Prognosis

Floppy mitral valve syndrome is an entirely benign condition in the great majority of patients. This is particularly so in children, where associated significant valvar regurgitation is rarely seen, outside those having a co-existing disorder of connective tissues. Looking beyond the paediatric age range into adulthood, patients are stratified according to whether they have risk factors such as significant valvar regurgitation, left ventricular dysfunction, left atrial dilation, a flail leaflet, or atrial fibrillation.^{90,91} Progressive regurgitation occurs in approximately one-sixth of adults over a period of 10 to 15 years.⁹² Such patients usually have thick and redundant leaflets and are usually male and over 50 years of age. Although infective endocarditis occurs more frequently in the setting of the regurgitant valve,⁹³ the current guidelines from the American Heart Association do not ask for antibiotic prophylaxis.

Sudden death has been reported in those with prolapsing valves, albeit that the cause and effect is unclear. At the best, it could be stated that those cases with severe valvar regurgitation, or complex arrhythmias, are at a higher risk of sudden events.

Management

For children with normal T waves and QT interval, no evidence of Marfan's syndrome, and with only a valvar click, review over periods of 5 years is suitable treatment. It is not necessary to prescribe prophylaxis against bacterial endocarditis, even if there is evidence of valvar regurgitation. Children with inversion of the T waves in leads II, III, aVF, V₅ or V₆, or prolongation of the QTc interval, and those with a family history of premature sudden death and the click/murmur syndrome, should undergo 24-hour electrocardiographic monitoring, which must be compared against standards for normal individuals of their age. If this shows ventricular tachycardia or fibrillation, or if there are significant symptoms and an abnormally high incidence of premature ventricular contractions, then it is sensible to begin antiarrhythmic therapy. The frequency of follow-up should be adjusted according to the response. If the 24-hour electrocardiogram is within normal limits, annual follow-up is sufficient, repeating the 24-hour monitoring only if indicated by symptoms such as dizziness or syncope, or if the incidence of arrhythmias increases as seen in the standard electrocardiogram.

Parents of children with a persistent late systolic murmur should be advised of the small chance of progressive mitral regurgitation, which might necessitate surgery in adulthood. These patients should be followed on an annual basis, performing an echocardiogram to reassess the severity of regurgitation, as well as left ventricular function and left atrial size.

Surgical management for those with significant valvar regurgitation is similar to that for adults. Prolapse of

the mural leaflet, or one of its scallops, presages a better outcome than evidence of prolapse of the aortic leaflet. Quadrangular resection of the involved segment of the mural leaflets is undertaken, with or without a sliding plasty. For those with prolapse of the aortic leaflet, it is possible to perform a triangular resection, as well as shortening and transfer of the tendinous cords. As well as resection of parts of the leaflets, it may be necessary to perform annuloplasty or insert an annular ring. Although the results of surgical repair are very good, recurrent regurgitation occurs in a subset of patients, necessitating replacement of the valve.

CHAPTER 36

Tetralogy of Fallot with Pulmonary Stenosis

CHRISTIAN APITZ, ROBERT H. ANDERSON, and ANDREW N. REDINGTON

Even though, as stated by Lev and Eckner,¹ no two cases are exactly the same, it is the characteristic anatomy that permits the instant recognition of the tetralogy of Fallot. As was emphasised by Arthur Louis Etienne Fallot, as long ago as 1888, all cases have an interventricular communication, biventricular origin of the aorta, muscular obstruction within the right ventricular outflow tract, and right ventricular hypertrophy (Fig. 36-1). There is no question but that hearts with this phenotypic morphology had been described long before Fallot emphasised the constellation of lesions that now bears his name. Thus, according to Marquis,² the malformation was first described in 1673 by the Danish monk, Nicholas Steno, in an ectopic heart from a fetus. Fallot deserves his eponym, nonetheless, since it was he who first observed that the combination of lesions accounted for the majority of cases of *la maladie bleue*, or cyanosis, which he encountered at autopsy. Abbott,³ in her classic *Atlas of Congenital Cardiac Disease*, emphasised the observations of Fallot,³ and the eponym has continued

to retain favour since her own descriptions of permanent cyanosis. Arguments have continued, however, as to the essence of the malformation, and which variants should be described with the eponym. Thus, when obstruction within the right ventricular outflow tract is minimal, it can be hard to distinguish tetralogy from the variant of ventricular septal defect with aortic overriding known as the Eisenmenger defect,⁴ even using anatomic criteria.⁵ When obstruction is complete, the condition unequivocally represents the commonest variant of pulmonary atresia with ventricular septal defect, although not all accept that this form should be described as tetralogy with pulmonary atresia. The phenotypic feature that underscores the existence of the tetralogy is anterior and cephalad deviation of the septal insertion of the outlet septum relative to the septo-marginal trabeculation, combined with an arrangement of the septoparietal trabeculations that produces an annular obstruction at the mouth of the infundibulum. Within the collection of hearts unified in this fashion, there is ample room for significant individual variation, as emphasised by Lev and Eckner.¹ It is this variation that will be the focus of our anatomic discussions in this chapter, with emphasis placed on the major differences from the normal heart.

Figure 36-1 The photograph, taken from the apex of the morphologically right ventricle looking towards the base, shows the phenotypic features of tetralogy of Fallot. Note that the muscular outlet septum, separating the overriding component of the aortic outlet from the subpulmonary (subpulm.) infundibulum, is inserted to the antero-cephalad limb of the septomarginal trabeculation (yellow Y).

INCIDENCE, PREVALENCE, AND AETIOLOGY

Of infants born with congenital heart disease, approximately 3.5% will have tetralogy of Fallot, giving a figure of 0.28 per 1,000, or 1 in 3,600, live births.⁶ Males and females are equally affected. According to existing statistics, the frequency increases with age when compared with other forms of cyanotic congenital cardiac malformations. This is largely because, in the past, infants with more lethal cardiac anomalies tended to die, whereas many with tetralogy of Fallot survive beyond infancy even without treatment. This could well change in the current era.

As with so many congenital cardiac anomalies, precise aetiology is unknown. The majority of cases are sporadic. According to Nora and colleagues,⁷ the risk of recurrence in siblings is about 3% if there are no other affected first-degree relatives. Rubella in the first trimester of pregnancy has been implicated in a small number of cases,⁸ while viruses have been isolated from cases with severe pulmonary arterial hypoplasia.⁹ Keeshond dogs were bred to produce a spectrum of inherited malformations of the ventricular outflow tracts, which included anomalies similar to tetralogy of Fallot.¹⁰ The findings indicated a polygenic model of inheritance, in which the genes act additively to produce the spectrum of maldevelopment. The lesion is also known to be linked with abnormal migration of cells from the neural crest. Dosage of rats with bis-diamine,

known to inhibit migration from the neural crest, produces the phenotypic features of tetralogy when given at critical periods of development, including cases with pulmonary atresia rather than stenosis.^{11,12} In a significant proportion of cases, it is possible to find microdeletions of the q11 region of chromosome 22, such deletions being known to produce Di George syndrome and the velocardiofacial syndrome, also known as the conotruncal anomaly face syndrome.¹³ In some series,¹⁴ microdeletion was found in up to a quarter of cases, suggesting that investigation using fluorescent in situ hybridisation should be undertaken in all patients with the phenotypic features of tetralogy.

Almost all those born with tetralogy of Fallot in all its variants can now expect to survive surgical correction, and reach adult life. Female patients may well ask the question 'Is it safe for me to become pregnant?', while both women and men will wish to know the risks of their progeny inheriting the condition. It has been known for some time that the incidence of congenital cardiac disease is higher in children born to women with congenitally malformed hearts than in the normal population,¹⁵ albeit that, with respect to tetralogy, no differences are found in the incidence of affected children according to whether it is the mother or father who had the lesion initially. According to some, the risk is approximately one-tenth for the offspring being affected. This risk is as for any congenital cardiac malformation, including minor lesions not requiring intervention.¹⁶ The risk is much higher, at above two-fifths, however, if the affected parent has a sibling with the same or a similar cardiac anomaly. Identification of those patients having microdeletion of chromosome 22q11 could well allow refinement of these calculations for risk of recurrence.

ANATOMY AND MORPHOGENESIS

Phenotypic Features

The phenotypic feature of the lesion is antero-cephalad deviation of the insertion of the muscular outlet septum relative to the limbs of the septomarginal trabeculation, coupled with an arrangement of the septoparietal trabeculations which produces a squeeze at the mouth of the infundibulum¹⁷ (Fig. 36-2). In the normal heart, the muscular outlet septum is an insignificant structure, inserted and buried between the limbs of the prominent septomarginal trabeculation. Indeed, it is so fully incorporated into the septum (Fig. 36-3) that it is not possible to distinguish an anatomically discrete outlet septal component from the dominant part of the supraventricular crest, which is the ventriculo-infundibular fold, itself supporting the free-standing subpulmonary infundibulum (Fig. 36-4). In tetralogy, these components of the supraventricular crest are divorced one from the other, with the right ventricular muscular outlet septum, rather than the ventriculo-infundibular fold, now supporting the narrowed free-standing subpulmonary infundibulum (Fig. 36-5).

Because of the abnormal position of the outlet septum, which is exclusively a right ventricular structure in tetralogy, the interventricular communication is situated between the limbs of the septomarginal trabeculation, whilst the right ventricular origin of the overriding aortic valve is supported by the ventriculo-infundibular fold (see Fig. 36-1). These three anatomic features of the tetralogy, therefore, all reflect the abnormal location of the outlet septum.

Figure 36-2 The heart has been sectioned to replicate the oblique subcostal echocardiographic cut, and shows the phenotypic feature of tetralogy, namely insertion of the muscular outlet septum antero-cephalad relative to the limbs of the septomarginal trabeculation (yellow Y), together with an abnormal arrangement of the septoparietal trabeculations. The abnormalities combine to produce an annular obstruction at the mouth of the subpulmonary infundibulum (yellow bracket).

Figure 36-3 The subpulmonary outflow tract of the normal heart is opened to show how the supraventricular crest, the muscular fold separating the attachments of the tricuspid and pulmonary valves, is inserted between the limbs of the septomarginal trabeculation (yellow Y). Note the location of the septoparietal trabeculations.

This particular phenotypic combination, nonetheless, cannot be produced in the absence of the squeeze produced together with the septoparietal trabeculations, which are themselves often hypertrophied, particularly in hearts from older patients. The outlet septum, nonetheless, can be markedly deviated in antero-cephalad direction without there being subpulmonary stenosis, despite the presence

Figure 36-4 Another normal heart has been dissected to show that the greater part of the supraventricular crest is the ventriculo-infundibular fold, or inner heart curvature, supporting the free-standing subpulmonary infundibulum. A small part of the septum can be resected to gain entrance to the left ventricle, but there are no anatomic landmarks delineating this from the inner heart curvature. The yellow Y shows the septomarginal trabeculation.

Figure 36-6 This heart has been sectioned in the same plane as that shown in Figure 36-2. There is again antero-cephalad deviation of the insertion of the muscular outlet septum, but in this instance without producing muscular subpulmonary (subpulm.) obstruction. This is the Eisenmenger defect, but not an example of tetralogy of Fallot.

Figure 36-5 The adjacent parts of the subaortic and subpulmonary outlets have been removed from a heart with tetralogy of Fallot. The section shows how the narrowed subpulmonary infundibulum is made up of the outlet septum (star) and the free-standing infundibular sleeve (double-headed arrow). Note the tissue plane (dots) between the infundibulum and the aortic root.

of hypertrophied septoparietal trabeculations, as in the so-called Eisenmenger complex (Fig. 36-6).

Although the divorce of outlet septum, ventriculo-infundibular fold, and septomarginal trabeculation are the essence of tetralogy when combined with the annular muscular obstruction at the mouth of the subpulmonary infundibulum, and despite the fact that each can be recognised anatomically in its own right, there has been significant previous confusion and controversy in description of the abnormal outflow tracts. This is because each of these three structures, at various times and in various places, had been nominated as a component of the so-called

crista. Consequently, when alleged parts of the crista were described in the setting of tetralogy, it was difficult to be sure which of the different structures was being described. Because of these problems, we suggested quite some time ago¹⁸ that the term crista, or its translation as supraventricular crest, be reserved for description of the muscular structure separating the attachments of the leaflets of the tricuspid and pulmonary valves in the normal right ventricular outflow tract (Fig. 36-7). In situations where the muscular structures are separated one from the other, as is the case in tetralogy, we suggested that each structure be accounted for in its own right, using descriptive and mutually exclusive terms (Fig. 36-8). This suggestion has since stood well the test of time. Thus, the outlet septum is any muscular or fibrous structure that interposes between the subpulmonary and subaortic outflow tracts. This septum has septal and parietal insertions, and is contiguous with the sleeve of free-standing subpulmonary infundibular musculature, albeit that the infundibulum itself is absent when the outlet septum is exclusively a fibrous structure. The ventriculo-infundibular fold, being part of the muscular inner heart curvature, is any muscular structure that separates the leaflets of an arterial from an atrioventricular valve. It is the extensive trabeculation reinforcing the septal surface of the morphologically right ventricle that is nominated as the septomarginal trabeculation, or septal band. It has a body, together with anterior-cephalad and postero-caudal limbs, the latter components usually supporting the inferior margin of the interventricular communication, not only in tetralogy, but also in other lesions such as double outlet right ventricle and common arterial trunk. The moderator band arises apically from its body, and crosses to the free ventricular wall. The moderator

Figure 36-7 The cartoon shows the building blocks of the outflow tract of the normal right ventricle. Note, however, that it is impossible to distinguish between the outlet septum and the ventriculo-infundibular fold in the normal situation without resorting to dissection (see Figs. 36-3 and 36-4). The stars show the location of the septoparietal trabeculations.

Figure 36-8 The cartoon shows how the building blocks of the normal outflow tract (see Fig. 36-7) come apart one from the other in the setting of tetralogy of Fallot. The subpulmonary (subpulm.) obstruction is produced by a squeeze between the muscular outlet septum and the most distal of the septoparietal trabeculations. As in Figure 36-7, the stars show the septoparietal trabeculations.

Figure 36-9 This specimen with tetralogy of Fallot has been sectioned to replicate the oblique subcostal echocardiographic cut. It shows how the building blocks of the outflow tract can readily be distinguished and described.

band is, however, only one of a series of muscle bars which extend to the parietal wall. The others are the septoparietal trabeculations, an integral component of the normal heart, but forming an integral part of the obstruction to the pulmonary pathways seen in tetralogy. Use of these terms makes it a simple matter to describe and differentiate the muscular structures forming the outflow tracts in tetralogy of Fallot (Fig. 36-9).

Variability in the Margins of the Ventricular Septal Defect

The hole between the ventricles is directly beneath the overriding aortic valvar orifice. It can thus be considered an outlet defect. The muscular outlet septum itself, however, is usually well-formed, albeit malaligned relative to the rest of the muscular septum. Indeed, as already discussed, part of the essence of tetralogy is antero-cephalad deviation of the septal insertion of the outlet septum such that it becomes a right ventricular rather than an interventricular structure, this deviation co-existing with the abnormal arrangement of the most distal septomarginal trabeculation (see Figs. 36-2 and 36-9). It is the outlet septum, therefore, and its fusion with the antero-cephalad limb of the septomarginal trabeculation, which forms the anterior margins of the defect. The crest of the muscular ventricular septum, reinforced by the limbs of the septomarginal trabeculation, forms the floor of the defect. Because of the septal malalignment, the roof of the defect is formed by the attachments of the leaflets of the overriding aortic valve to the ventriculo-infundibular fold. Indeed, because of the overriding of the aortic orifice, problems exist in defining specifically the nature of the ventricular septal defect. Any one of a host of planes within the cone of space subtended from the valvar leaflets to the crest of the septum can be nominated as a septal defect (Fig. 36-10).

When describing the boundaries of these planes, we concentrate on the margins of the cone as viewed from the right ventricle,¹⁹ since this is the locus along which the surgeon will attach the patch used to repair the malformation so as to reconstitute the ventricular septum (see Fig. 36-10). When the ventricular septal defect is defined in this fashion, it is the postero-inferior quadrant that shows most anatomic variability. In about four-fifths of cases, this margin is formed by fibrous continuity between the leaflets of the aortic, mitral and tricuspid valves (Fig. 36-11).

Figure 36-10 The cartoon shows three planes within the cone of space subtended from the crest of the ventricular septum to the attachments of the overriding aortic valve that could be defined as the ventricular septal defect. The red disc is the outlet from the left ventricle, whilst the yellow disc represents the continuation of the muscular ventricular septum. It is the green disc, however, that we describe as the ventricular septal defect, since this is the locus along which the surgeon will place the patch to reconstitute the ventricular septum.

Figure 36-11 The illustration shows the morphology of the commonest type of interventricular communication found in the setting of tetralogy of Fallot. There is fibrous continuity between the leaflets of the aortic and tricuspid valves in the postero-inferior margin of the defect, making it perimembranous. The yellow Y shows the septomarginal trabeculation.

In this respect, the defect is directly comparable to typical perimembranous defects opening to the outlet of the right ventricle in the absence of subpulmonary obstruction. In our view, it is unnecessary to consider the defect in tetralogy

as a separate entity should it co-exist with malalignment of the outlet septum. In that the postero-inferior margin is an area of fibrous continuity between the leaflets of the aortic and tricuspid valves, the defect is unequivocally perimembranous. These anatomic features are reflected in the distribution of the atrioventricular conduction tissues. As in all other hearts with concordant atrioventricular connections, the guides to the location of the atrioventricular node are the landmarks of the triangle of Koch. The penetrating bundle perforates the central fibrous body through the area of valvar continuity (Fig. 36-12). Here, the bundle is frequently overlaid by a remnant of the interventricular membranous septum, which may on occasions become aneurysmal. The septal remnant itself, called the membranous flap,²⁰ is safe tissue for anchorage of sutures when such stitches are placed with care.²¹ It is positioned, however, directly superficial to the penetrating bundle.²² Sutures placed deeply in this area are liable to produce complete heart block. It is safer, therefore, to place sutures through the leaflet of the tricuspid valve, which usually overlaps the membranous flap in this area of the defect. Having perforated, the nonbranching atrioventricular bundle enters the left ventricular part of the aortic outflow tract, and almost always then veers away from the septal crest, the branching atrioventricular bundle being carried on the left ventricular

Figure 36-12 The heart illustrated has been prepared by removing the septal leaflet of the tricuspid valve, revealing the crest of the muscular ventricular septum, reinforced by the limbs of the septomarginal trabeculation. Note the mouth of the infundibulum (yellow bracket), squeezed between the deviated outlet septum and the hypertrophied septoparietal trabeculation (star). The location of the atrioventricular node at the apex of the triangle of Koch (cross-hatched red oval), the penetrating, non-branching and branching components of the axis (yellow dotted line). The left bundle branch, taking origin below the crest of the septum, is shown in the blue-green dashed lines. The axis then penetrates back through the septum (continuation of yellow dotted line beyond the green dashed lines), before surfacing beneath the medial papillary muscle and continuing as the right bundle branch within the body of the septomarginal trabeculation (red line).

Figure 36-13 In this patient with tetralogy of Fallot and a perimembranous septal defect, the surgeon placed the stitches to secure the patch through the crest of the ventricular septum, as was recommended at that time. As can be seen, one of the stitches has produced an area of haemorrhage on the left ventricular aspect of the septal crest, and as shown by the histological section, the haemorrhage is contained within the non-branching atrioventricular bundle (red arrow in inset). The open arrow in the inset shows the bite of the suture through the septal crest.

aspect of the septum and staying remote from the septal crest. In a minority of hearts, nonetheless, the bundle may branch directly astride the septum. Such an arrangement places the bundle at risk should sutures be placed into the crest of the septum (Fig. 36-13). Irrespective of these differences, the right bundle branch penetrates back through the septum, emerging within the postero-caudal limb of the septomarginal trabeculation and then descending within its substance towards the apex.

The second most common pattern, occurring in about one-fifth of cases, is characterised by interruption of the area of fibrous continuity between the aortic and tricuspid valves by a muscular fold.^{17,19} When viewed from its right ventricular aspect, therefore, the septal defect has exclusively muscular rims. The fold itself is formed by fusion of the postero-caudal limb of the septomarginal trabeculation with the ventriculo-infundibular fold. An intact membranous septum is found between the muscular fold and the remaining atrioventricular septal structures. Since the atrioventricular conduction axis runs postero-inferior to the membranous septum, the muscular fold, together with the membranous septum itself, separates the conduction tissues from the crest of the ventricular septum (Fig. 36-14). When the muscular fold is of good dimensions, as is usually the case, the entire muscular margins of the defect are suitable for anchorage of sutures, provided that the stitches are not placed too deeply.

There is then yet a third variety of defect, characterised by presence of a fibrous rather than a muscular outlet septum, and absence of the free-standing subpulmonary infundibular sleeve.^{17,19} This is the doubly committed and juxta-arterial defect, by far the least common in the Western World, but commoner in the Far East and South America. The defect is both subaortic and subpulmonary as a consequence of failure of formation of the muscular subpulmonary

Figure 36-14 In this heart from a patient with tetralogy of Fallot, the postero-caudal limb of the septomarginal trabeculation (yellow Y) fuses with the ventriculo-infundibular fold (vent-inf. fold) in the postero-inferior margin of the defect. This protects the conduction axis (yellow dotted lines). Note the hypertrophied septoparietal trabeculations (stars).

Figure 36-15 In this heart from patient with tetralogy of Fallot, the interventricular communication is roofed by fibrous continuity between the leaflets of the arterial valves, making it doubly committed, and also extends to an area of fibrous continuity between the aortic and tricuspid valves, the ventriculo-infundibular fold (vent-inf. fold) stopping short of the postero-caudal limb of the septomarginal trabeculation (yellow Y). Because the defect extends to become perimembranous, the conduction axis is at potential risk in its postero-inferior margin (yellow dotted line). Note the remnant of the interventricular membranous septum, which forms the so-called membranous flap. Note also the deviated fibrous outlet septum in the roof of the defect.

infundibulum. Such defects can also be found with fibrous continuity between the leaflets of the aortic and tricuspid valves, making them perimembranous (Fig. 36-15), but more usually there is a muscular postero-inferior rim, comparable to the muscular structure seen in Figure 36-14. If present, the muscular structure will protect the atrioventricular conduction axis, but in the heart shown in Figure 36-15, the conduction axis will be at direct risk in the postero-inferior margin of the defect.

Patients with tetralogy, of course, all possess defects as described above, which open between the outflow tracts. They can also be encountered with additional defects

elsewhere in the septum. Inlet defects are particularly important, be they muscular inlet defects, defects associated with straddling and overriding of the tricuspid valve, or the ventricular component of an atrioventricular septal defect associated with common atrioventricular junction. The combination of tetralogy and an atrioventricular septal defect with common atrioventricular junction, in the past, was considered to pose significant additional problems to the surgeon, but these difficulties have now been overcome in most centres of excellence. Almost always in tetralogy, the ventricular septal defect is large, approximating in size the diameter of the aortic root. Rarely, it may be restrictive due to the presence of accessory fibrous tissue tags formed at the margins of the defect. Such tags may be derived in part from the tricuspid valve, or extend from attachment of the tension apparatus of the mitral valve across the left ventricular aspect of the defect.

Narrowing of the Subpulmonary Infundibulum

The subpulmonary stenosis, which is an essential part of tetralogy, is due to the squeeze between the antero-cephalad deviation of the outlet septum and the abnormal arrangement of the distal septoparietal trabeculations, this being the phenotypic feature of the lesion (see Figs. 36-2 and 36-9). The antero-cephalad component of the obstruction, therefore, is produced by the septoparietal trabeculations, often additionally hypertrophied, which extend onto the ventricular free wall. These muscular bundles can be removed by the surgeon without fear of causing damage to significant structures. The maximal area of stenosis, when viewed from the apex of the right ventricle, produces an obvious mouth to the subpulmonary infundibulum, the so-called os infundibulum (Fig. 36-16).

Additional stenosis can then be found more proximally within the ventricle, produced either by hypertrophy of the moderator band, which is one of the septoparietal trabeculations, or by prominent apical trabeculations. This gives the arrangement often described as two-chambered right ventricle. The subpulmonary infundibulum itself, distal to the squeeze between outlet septum and septoparietal trabeculations, varies markedly in length. In some instances, when the ventricular septal defect is doubly committed, the infundibulum is no longer an exclusively muscular structure (see Fig. 36-15). In other instances, the narrowed infundibular chamber has considerable length (see Fig. 36-16). There is a spectrum between these extremes, but measurements of series of hearts from patients with tetralogy,²³ when compared to measurements of normal hearts, show that the infundibulum is longer in the setting of the malformation (Fig. 36-17). In addition to the muscular stenosis, it is also usual to find obstruction at valvar level, with the valve itself often possessing two rather than three leaflets. Further stenotic lesions can then be found within the pulmonary arterial pathways.

Overriding of the Aortic Valve

In the normal heart, although the right aortic sinus of the aortic valve overrides spatially the crest of the muscular ventricular septum, the leaflets of the valve are attached exclusively within the left ventricle. Whenever the ventricular septum is deficient, however, part of the circumference of the aortic valvar orifice of necessity becomes attached to, and supported by, right ventricular structures.²⁴ Such aortic overriding becomes more obvious when the outlet

Figure 36-16 This picture was taken in the operating room during surgical correction of a patient with tetralogy of Fallot. The photograph has been reorientated in an anatomically appropriate fashion. It shows the narrow mouth of the subpulmonary infundibulum in this patient, the infundibulum itself having significant length. (Courtesy of Dr Benson Wilcox, University of North Carolina, Chapel Hill.)

Figure 36-17 Measurements of the length of the subpulmonary infundibulum in 16 patients with tetralogy of Fallot, and 14 normal hearts, taking the length of the right ventricle as unity. The difference in the lengths, in favour of the patients with tetralogy, was highly significant statistically. Values taken from Becker and colleagues.²³

septum is deviated so as to become exclusively a right ventricular structure, as in tetralogy of Fallot (see Fig. 36-1) or the Eisenmenger ventricular septal defect (see Fig. 36-6). The precise degree of override, in other words the proportion of the aortic valvar circumference supported by right as opposed to left ventricular structures, can therefore vary between 5% and 100%. This feature has obvious surgical

Figure 36-18 In this heart with the phenotypic features of tetralogy of Fallot, the bracket showing the squeeze at the mouth of the infundibulum between the outlet septum and the septoparietal trabeculations, the overriding aorta is supported almost exclusively in the right ventricle. The patient, therefore, has double outlet ventriculo-arterial connections. Note that in this particular heart, the ventriculo-infundibular fold has persisted between the leaflets of the aortic and mitral valves, so the patient also has a completely muscular subaortic infundibulum, albeit that the ventricular septal defect is perimembranous because of fibrous continuity between the leaflets of the mitral and tricuspid valves.

significance. A much larger patch will be required to reconstitute the ventricular septum, and connect the aorta to the left ventricle, when the larger part of its circumference is supported by the right ventricle. Care must be taken to be sure that the patch is not placed so tightly as to obstruct the newly created left ventricular outflow tract.

This feature also has implications for nomenclature, albeit that the importance has been somewhat exaggerated. As has been explained in Chapter 1, we describe the situation in which more than half of the circumferences of both great arterial valves are connected in the same ventricle as double outlet ventriculo-arterial connection. In the context of tetralogy of Fallot, in which the entirety of the pulmonary valve is supported by the right ventricular subpulmonary infundibulum, if more than half of the leaflets of the aortic valve are hinged from right ventricular structures, we describe the situation as tetralogy of Fallot co-existing with the ventriculo-arterial connection of double outlet ventricle. There is no reason why the two should not co-exist. Double outlet is simply one particular ventriculo-arterial connection. Tetralogy of Fallot is defined on the basis of its phenotypic feature, namely antero-cephalad deviation of the outlet septum combined with hypertrophy of the septoparietal trabeculations. These two features, self-evidently, are not mutually exclusive (Fig. 36-18).

Other Lesions of the Pulmonary Circulation

Although the subpulmonary infundibulum is usually the narrowest part of the pulmonary outflow tract, other lesions are to be found elsewhere in the outflow tracts and the pulmonary arteries. Pulmonary valvar stenosis is a frequent accompaniment. This is sometimes due to domed stenosis, more frequently to stenosis of a bicuspid valve or to stenosis of a valve with three leaflets. The valvar lesion is rarely the major cause of obstruction, albeit that in some young infants

Figure 36-19 The illustration shows tetralogy of Fallot with so-called absence of the leaflets of the pulmonary valve. In reality, the leaflets form an annular rudimentary array at the ventriculo-arterial junction. Note the dilation of the pulmonary trunk and its branches, albeit that the ventriculo-arterial junction itself is narrowed.

it can be the predominant finding. The valve can also become imperforate as an acquired change. So-called absence of the leaflets of the pulmonary valve is another important lesion. Most usually, the valve is represented by an annular array of fibrous rudiments, usually found with dilation of the pulmonary trunk and its branches (Fig. 36-19).

Stenoses within the pulmonary arteries themselves are of major surgical significance, and usually occur at branching sites from the bifurcation outwards. Lack of origin of one pulmonary artery, typically the left, from the pulmonary trunk is by no means infrequent. The isolated pulmonary artery is almost always present, usually being connected by the arterial duct, or ligament, to some part of the system of aortic arches. Rarely, one pulmonary artery may arise directly from the ascending aorta, but then it tends to be the right one which is anomalously connected. Major systemic-to-pulmonary collateral arteries are sometimes present in association with tetralogy and pulmonary stenosis, but in association with normal right and left pulmonary arteries. Such arteries can be the sole source of pulmonary arterial flow when tetralogy co-exists with pulmonary atresia (see Chapter 37).

Associated Anomalies

Many other lesions can co-exist with tetralogy. Patency of the oval foramen is common, and a deficiency of the floor of the oval fossa is far from infrequent. In addition to a second inlet muscular ventricular septal defect, straddling of the tricuspid valve, or presence of a common atrioventricular valve, features already emphasised, the most important associated lesion from the stance of the surgeon is probably anomalous origin of the anterior interventricular coronary artery from the right coronary artery. A right aortic arch, though not of functional importance, is also common. When detected, it alerts to the diagnosis of tetralogy. Aortic incompetence is commoner in older patients.

Morphogenesis

The notion that tetralogy of Fallot reflects malseptation of the arterial segment of the developing heart has a long pedigree, and is supported by observations concerning naturally occurring infundibular lesions in Keeshond dogs.¹⁰ These animals show a spectrum of malformations, ranging from absence of the medial papillary muscle, through presence of a ventricular septal defect, to a constellation of anomalies similar to tetralogy. Study of embryos, in which developmental stages of these malformations were observed, showed that the factory for production of the lesions was within the ventricular outflow tracts. Specifically, abnormalities were found in the formation and position of the endocardial cushions which normally fuse to septate the ventricular outlets. These observations have now been confirmed in rats dosed with bis-diamine,^{11,12} while the concept of muscularisation of the proximal outflow cushions to form the subpulmonary infundibulum of the normal heart has been confirmed by observations in the developing human heart (Figs. 36-20 and 36-21).

The findings in patients with deletion of chromosome 22q11 also support the existence of malseptation of the outflow tracts in humans, and point to this being due to problems in migration of cells from the neural crest. Based on the anatomic findings, therefore, it can be said with some degree of certainty that there is malseptation of the ventricular outlets and the arterial pole of the heart at the expense of the pulmonary trunk, together with failure of normal incorporation of the aortic outflow tract into the morphologically left ventricle. As discussed, the abnormal attachment of the muscular outlet septum is sufficient to account for the presence of the interventricular communication and the biventricular connection of the aorta, but production of subpulmonary muscular stenosis requires an additional abnormality involving the septoparietal trabeculations. The right ventricular hypertrophy is simply a haemodynamic consequence of the anatomic lesions.

Figure 36-20 This section, from a human embryo just prior to closure of the embryonic interventricular communication (*double-headed arrow*) shows muscularisation of the proximal outflow cushions, which are about to fuse with the muscular interventricular septum so as to wall the aorta into the left ventricle.

Figure 36-21 This section comes from another human embryo, just after the completion of ventricular septation. It shows how the muscularised outflow cushions, with normal development, form the supraventricular crest of the right ventricle. After normal development, the outflow to the pulmonary trunk is unobstructed (*yellow bracket*). It is easy to see how, with malseptation of the outflow tracts, the cushions will form the muscular outlet septum and with hypertrophy of the septoparietal trabeculations produce the phenotypic morphology of tetralogy of Fallot.

Clinical Diagnosis

The clinical presentation is dominated by the degree of muscular obstruction of the right ventricular outflow tract.²⁵ This is sometimes modified by associated anomalies, such as persistent patency of the arterial duct, or presence of large systemic-to-pulmonary collateral arteries.

Presentation When Subpulmonary Obstruction Is Severe from Birth

When the obstruction of the right ventricular outflow tract is severe at birth, presentation is in the neonatal period. Persistent cyanosis becomes apparent within the first few hours or days of life. With severe arterial desaturation, a metabolic acidosis develops that is compensated by an increased respiratory rate. The concomitant fall in arterial content of carbon dioxide gives rise to a compensatory respiratory alkalosis. Intercostal or subcostal recession, however, is unusual. Cyanosis, which dominates the clinical picture, increases with crying, feeding, or other activities. At least initially, the baby does not appear unduly distressed. Sometimes the pulmonary circulation is duct-dependent. In this setting, the degree of subpulmonary obstruction is so great that there is inadequate antegrade flow, and virtually all pulmonary blood flow is derived from a left-to-right shunt via the arterial duct. Under such circumstances, spontaneous closure of the duct results in death. Maintenance of ductal patency, usually by infusion of prostaglandin E, is crucial.

Presentation When Subpulmonary Obstruction Is Moderate at Birth

The majority of children with tetralogy of Fallot are acyanotic at birth. Consequently, they often present because a systolic murmur is detected during routine examination. The development of cyanosis is dependent on increasing infundibular stenosis, and not on the degree of aortic override.²⁶ This is usually noted within the first few weeks of life, but development of cyanosis may rarely be delayed to late childhood. The systolic murmur, present in all patients other than those

with very severe stenosis or acquired atresia, originates at the site of subpulmonary obstruction, and not because of flow across the ventricular septal defect.²⁷ At this stage, infants or children are usually asymptomatic. Later, hypercyanotic spells or squatting on exercise may all occur. With improved medical surveillance, all of these symptoms are now less often encountered than even a decade ago.

Presentation When Subpulmonary Obstruction Is Minimal at Birth

Some infants with tetralogy may uncommonly present at the age of 4 to 6 weeks with features indistinguishable from those of a large ventricular septal defect (see Chapter 28). These babies are breathless, feed poorly, gain weight poorly, and are not cyanosed. With increasing right ventricular hypertrophy, the subpulmonary obstruction becomes more marked and, as the shunt is reversed, the patients exhibit the signs and progression as described for the group with moderate obstruction.

Presentation with Absent Pulmonary Valve

When tetralogy is complicated by so-called absence of the leaflets of the pulmonary valve, which are usually present in rudimentary form (see Fig. 36-19), the presentation is characteristic yet different from the previously described groups. The majority with this complication present in infancy with respiratory symptoms of inspiratory and expiratory stridor, dyspnoea caused by lobar collapse or, at times, lobar emphysema. These features reflect compression of the bronchial tree by the grossly dilated proximal pulmonary arteries. While bronchial obstruction may lead to lobar collapse, and subsequent infection, partial obstruction may produce a ball-valve effect, resulting in emphysema. Because there is stenosis at the site of the rudimentary leaflets of the pulmonary valve, symptoms directly related to abnormal haemodynamics are unusual.

Squatting

Squatting, along with other postures, may alleviate the degree of cyanosis, dyspnoea or feeling of faintness induced by exercise. The means by which squatting alleviates the symptoms of cyanosis and dyspnoea have caused considerable debate. Irrespective of the precise mechanisms, there is little doubt that squatting causes an abrupt increase in systemic venous return and a rise in systemic vascular resistance. Right-to-left shunting is decreased by an increase in systemic vascular resistance. This means that the volume of blood passing through the right ventricle to the lungs is proportionally increased, with immediate improvement in effective pulmonary flow, and hence arterial saturations of oxygen.

Hypercyanotic Attacks

An important, and often dramatic, feature of patients with tetralogy is the occurrence of unprovoked severe cyanosis, which may lead to reduced cardiac output, and be accompanied by transient loss of consciousness.²⁸ These episodes, which are most common between 6 months and 2 years of age,²⁹ are potentially dangerous, as they may lead to cerebral damage or even death.²⁸ The majority last between 15 and 60 minutes, but an individual spell may be of shorter duration, or can last for several hours. Initial presentation of infants or children may be with a history of episodic loss of consciousness, or convulsions, episodes of going floppy or pale, transient vacant episodes, or episodes of becoming deeply cyanosed followed by loss of consciousness or sleep. Another striking feature of these spells may be episodes of very rapid deep respiration or hyperpnoea, or a high-pitched abnormal cry. The episodes are usually sufficiently dramatic or unusual for parents to volunteer information, but specific

questioning concerning their presence should be part of every outpatient assessment. It was Wood (1958) who postulated that the spells resulted from infundibular spasm or shutdown.²⁸ Many now believe the concept of infundibular spasm, as a primary phenomenon, to be unsupported by the anatomy or physiology of the subpulmonary infundibulum, and suggest that the shutdown is secondary to other primary physiologic influences, such as dehydration, or tachycardia-induced reduction in right ventricular preload, systemic vasodilation in response to fever, or other sympathetic activity. Irrespective of their aetiology, their occurrence should lead to prompt treatment with continuous β -blockade, and referral for surgery or interventional catheterisation as dictated by the institutional protocols.

Physical Examination

The essential abnormal cardiac findings in the neonate with severe tetralogy of Fallot are cyanosis and, on auscultation, a systolic ejection murmur with a single second heart sound. Overt clubbing of fingers and toes is typically not detected until 2 or 3 months of age. The baby may be normally grown, although a higher proportion weighs less than would be expected by chance. Some degree of facial dysmorphism is quite common, and typical features of associated syndromes may be obvious, such as the DiGeorge, Goldenhauer, or Down syndromes. All patients should now undergo chromosomal analysis on presentation, with specific fluorescent *in situ* hybridisation for 22q11 deletion. Pulses are almost always normal in all limbs, aortic coarctation being exceedingly rare in symptomatic neonates with tetralogy of Fallot. The cardiac impulse may be normal, or the parasternal right ventricular impulse may be increased. The first heart sound is normal, but the second is characteristically single. In contrast to patients having pulmonary stenosis with an intact ventricular septum, pulmonary ejection sounds in the second or third intercostal space, or third and fourth heart sounds, are virtually never found in children with tetralogy. An aortic ejection click may sometimes be heard at the lower left sternal edge or at the apex. The duration of the systolic ejection murmur will vary depending on the degree of infundibular stenosis. The shorter the murmur, the tighter will be the stenosis and, in turn, the greater the cyanosis. Co-existing rudimentary formation of the leaflets of the pulmonary valve is characterised by an additional long loud early diastolic decrescendo murmur from pulmonary regurgitation, which should be easily distinguishable from a continuous murmur. When a loud continuous murmur is heard in the neonatal period, and clinical features are otherwise compatible with the diagnosis of tetralogy, it is more likely to originate from flow through large major systemic-to-pulmonary collateral arteries than the arterial duct. The patient is then likely to have co-existing pulmonary atresia. In these patients, cyanosis may not be so marked, since pulmonary blood flow is more adequately maintained through the collateral arteries.

Children with tetralogy in whom subpulmonary obstruction is minimal or absent at birth exhibit tachypnoea, dyspnoea, and intercostal or subcostal recession. This group has a large left-to-right shunt, with an increased flow of blood to the lungs. A prominent parasternal impulse, and hepatomegaly, may be present. On auscultation, the second sound is split, possibly with an accentuated pulmonary component.

Figure 36-22 The chest radiograph of this young infant presents the typical features of a patient with tetralogy of Fallot. The trachea is slightly compressed by the aorta arching to its right side. Instead of the normal convexity produced by the pulmonary trunk, a concavity, or pulmonary arterial bay, is present.

Investigations

While the diagnosis of tetralogy of Fallot is usually made from clinical assessment, confirmation is now provided largely by cross sectional echocardiography. Before describing the typical echocardiographic features, however, we will discuss the plain chest radiograph and the electrocardiogram, as these are usually carried out as part of the general cardiac assessment of a child.

Chest Radiograph

In the acyanotic patient with tetralogy, the plain chest radiograph may be normal. Most patients have the usual arrangement of thoracic and abdominal organs, together

with a left-sided heart, but tetralogy may occur with mirror-imaged arrangement, when the heart is usually right-sided. With usual atrial arrangement, up to one-third of patients with tetralogy have a right aortic arch. Of all subjects with a right aortic arch, three-quarters have tetralogy of Fallot with or without pulmonary atresia. The diagnosis is even more likely if there are reduced pulmonary vascular markings. Pulmonary vascular markings will usually be reduced in cyanotic patients, the lung fields being strikingly oligoemic in neonates when subpulmonary obstruction is severe. In contrast, vascular markings will be normal when infundibular stenosis is moderate. When subpulmonary obstruction is minimal, there will be pulmonary plethora, reflecting the left-to-right shunt. The heart is usually of normal size, but the upper right cardiac border may be prominent owing to displacement of the superior caval vein by a right aortic arch. A pulmonary bay, or concavity at the upper left heart border, reflects a small pulmonary trunk (Fig. 36-22). The apex of the heart may be upturned, probably because the hypertrophied right ventricle forms the apex in the postero-anterior projection. Post-operatively, the heart size can be used as a reasonable surrogate of right ventricular dilation, although other methods are clearly more accurate, and appropriate, for detailed assessment.

Electrocardiography

There is usually sinus rhythm, a normal or rightward QRS axis and overt right ventricular hypertrophy. After surgery, right bundle branch block with prolongation of the QRS duration is frequent.

Echocardiography

Transthoracic cross sectional echocardiography usually allows clear demonstration of all the intracardiac anatomy. As always, a sequential approach is used. The subcostal paracoronal view shows the narrowed subpulmonary outflow tract, with malalignment of the anteriorly displaced muscular outlet septum (Fig. 36-23). Parasternal long-axis

Figure 36-23 This echocardiogram shows a subcostal right anterior oblique view which presents an excellent overview of all the salient features of tetralogy. Panel A shows the classical subcostal right anterior oblique view and demonstrates marked trabeculations of the right ventricle (RV), antero-cephalad deviation of the outlet septum and narrowing of the right ventricular outflow tract. Panel B is a modified right anterior oblique view showing different anatomy in this case. The outlet septum (arrows) is elongated with lengthening of the subpulmonary infundibulum. Ao, overriding aorta; PA, pulmonary trunk; RA, right atrium.

Figure 36-24 The parasternal long-axis view demonstrates the aortic valve (Ao) overriding the crest of the muscular ventricular septum and marked hypertrophy of the right ventricular myocardium. LA, left atrium; LV, left ventricle; RV, right ventricle.

views demonstrate the aortic override (Fig. 36-24). Biventricular connection is seen also in the anteriorly tilted four-chamber view, but this is less reliable at defining the degree of override. If present, a straddling or overriding tricuspid valve is also seen in the four-chamber view, as is the common atrioventricular junction in hearts with deficient atrioventricular septation. These views, together with a parasternal short-axis view, allow the margins of the ventricular septal defect to be identified. The defect is usually perimembranous, but may have a muscular postero-inferior rim. The defect can also extend to become doubly committed and juxta-arterial when the outlet septum is fibrous and there is absence of the free-standing subpulmonary infundibulum. When the pulmonary trunk is traced to its bifurcation, it is possible to determine the size of the pulmonary arteries (Fig. 36-25) to the level of their first bifurcation, but not the more distal pattern of branching. Views of the aortic arch show the pattern of branching of the brachiocephalic arteries, a right brachiocephalic artery usually being found when the aortic arch is left-sided. When the first branch from the arch itself divides into left carotid and subclavian arteries, then it can be inferred that this vessel is the brachiocephalic

Figure 36-25 This echocardiogram in short-axis view shows the rudimentary nature of the leaflets of the pulmonary valve and narrowing of the pulmonary trunk (arrow) as well as markedly dilated left and right pulmonary arteries in a patient with so-called absent pulmonary valve.

Figure 36-26 This short-axis echocardiogram shows an anomalous artery (arrows) arising from the right coronary artery (RCA) and crossing the subpulmonary infundibulum. Ao, aorta.

artery, and that the arch itself is right-sided. These views will also show a persistent arterial duct, if present, while colour flow Doppler can confirm patency of previous palliative shunts, and may show collateral arteries. As with the echocardiographic assessment of all anomalies, it is essential to confirm normal systemic and pulmonary venous connections. Anomalous pulmonary venous connections in particular, if present, must be identified. Associated anomalies, such as rudimentary formation of the leaflets of the pulmonary valve, and dilation of the pulmonary trunk, are readily identified (see Fig. 36-25). In most patients, the origins of the right and left coronary arteries from the aorta can also be visualised, as can branching of the left artery into the circumflex and anterior interventricular arteries. Anomalous arteries can be identified crossing the subpulmonary infundibulum (Fig. 36-26), and their precise origin now determined. Similarly, the post-operative assessment of the early surgical result, the presence of residual lesions, and their haemodynamic sequels, are all well demonstrated by transthoracic echocardiography. The assessment of pulmonary regurgitation and its secondary effects on right ventricular performance can be assessed qualitatively, but for clinical decision making, there is an increasing reliance on magnetic resonance imaging, particularly in the teenager and adult.

Magnetic Resonance Imaging

With the exception of those with major aortopulmonary collaterals, there is rarely an indication for pre-operative cardiac studies using magnetic resonance imaging. Conversely, post-operative evaluation and decision-making are increasingly reliant on measurements obtained using this technique. Indeed, magnetic resonance imaging has rapidly become the gold standard for quantitative assessment of right ventricular volume, mass, and function, regardless of the position of the heart in the thorax.^{30,31} Spin echo, or black blood, sequences are used for exploration of anatomy, and gradient echo, or white blood, sequences are employed for assessment of right ventricular function (Fig. 36-27). Magnetic resonance imaging may give an unrestrictive view of the right ventricular outflow tract, and if present, any aneurysmal enlargement can be demonstrated

Figure 36-27 Magnetic resonance imaging in a patient with tetralogy of Fallot late after surgical correction. Cine-still-frame images of a four-chamber view show markedly dilated right ventricle (RV) and moderately dilated left ventricle (LV).

(Figs. 36-28 and 36-29). Volumetric analysis of the right ventricle is performed by manually drawing endocardial contours at end-diastole and end-systole (Fig. 36-30A). Ejection fraction is then calculated by dividing stroke volume, represented by the difference between end-diastolic and end-systolic volumes, by the end-diastolic volume.

By using velocity mapping, quantification of the flow of blood to the lungs allows for accurate calculation of the pulmonary regurgitant volume and fraction (Fig. 36-30B). The latter is less reliable as an index of right ventricular preload, although is often considered, incorrectly in some patients, to be proportional to severity. Resonance imaging also permits measurements to be made with precision. The diameter of the aortic root, and any aortic insufficiency, can be quantified, while the peripheral pulmonary arteries can be demonstrated with unsurpassed clarity

Figure 36-29 Magnetic resonance three-dimensional rendition in the late post-operative follow-up of a patient with tetralogy of Fallot demonstrates an aneurysmal right ventricular outflow tract (RVOT) (arrow) and left aortic arch (Ao).

(see Fig. 36-28). The distribution of flow between the right and left pulmonary arteries can be assessed, and the influence of arterial size and discrete stenoses, if present, can be quantified. Imaging of delayed enhancement using gadolinium can show any scarring or fibrosis of the ventricles, these lesions potentially contributing to an increased propensity for arrhythmias, or formation of aneurysms in the right ventricular outflow tract.

Cardiac Catheterisation and Angiography

In most large units, diagnostic cardiac catheterisation is now rarely performed prior to palliative or corrective surgery (Fig. 36-31). Those with multiple aortopulmonary collateral arteries are a frequent exception to this rule (see Chapter 37), but increasingly magnetic resonance imaging is used rather than angiography to delineate their anatomy and distribution. The role of cardiac catheterisation in such patients, therefore, is to assess the haemodynamics within, and

Figure 36-28 Magnetic resonance angiography and volume-rendered image shows hypoplasia of the right and left pulmonary arteries in a patient after repair of tetralogy of Fallot with additional distal arborisation abnormalities. Ao, Aorta; LPA, left pulmonary trunk; PT, pulmonary trunk; RPA, right pulmonary artery; RV, right ventricle.

Figure 36-30 Panel A shows multiple short-axis cines from the apex to the base of the heart which are used to quantify right ventricular and left ventricular volumes by epicardial and endocardial tracing. The *yellow lines* show the tracing of the endocardial surface of the right ventricle, while the *green* and *red lines*, respectively, show the epicardial and endocardial surfaces of the left ventricle. In this patient with dilated right ventricle following correction of tetralogy of Fallot, the indexed end-diastolic volume was calculated to be 275 mL/m² body surface area (BSA) and the indexed left ventricular volume was 140 mL/m² BSA. Panel B demonstrates a flow profile, acquired with velocity mapping of the pulmonary trunk, that can be created by outlining the pulmonary artery in all phases of a heart cycle. Pulmonary regurgitation and late diastolic forward flow are clearly shown.

connections between, the individual vessels when necessary. Interventional catheterisation remains applicable for some patients. Dilation and stenting of the right ventricular outflow tract, with prior radio-frequency perforation if atretic, have a role in some. Similarly, pre-operative balloon dilation of the pulmonary arteries, stenting of the arterial duct, and interventions on the aortopulmonary collateral arteries, may be part of a combined surgical and medical programme

of management, often with the need for additional post-operative interventions in the more challenging cases.

Haemodynamics and Physiology

The haemodynamic consequences of the lesion are dominated by the severity of obstruction within the subpulmonary right ventricular outflow tract, superimposed

Figure 36-31 Angiography of the right ventricle performed in right anterior oblique projection. The outlet (infundibular) septum (OS), profiled in cross-section, together with hypertrophied septoparietal trabeculations of the right ventricular free wall produce muscular subvalvar stenosis. The pulmonary trunk (PT) is seen, together with the size of the right and left pulmonary arteries (RPA, LPA, respectively). The aorta (AO) has been opacified by contrast passing through the ventricular septal defect. RV, right ventricle.

upon the presence of a large ventricular septal defect. In almost all patients, the interventricular communication is large and non-limiting. This results in equalisation of right and left ventricular systolic pressure, regardless of the severity of pulmonary stenosis. The relative flows in the pulmonary and systemic circuits depend on the relative resistances, or impedances, to emptying of the right and left ventricles. When right ventricular outflow obstruction is minimal, and the pulmonary vascular resistance is normal, the flow of blood to the lungs will exceed that in the systemic circuit. There will then be a dominant left-to-right shunt, and the clinical picture will resemble closely that of a ventricular septal defect. Under these circumstances, resting cyanosis may be absent. When obstruction to right ventricular emptying is similar to that provided by the systemic vascular resistance, a balanced situation exists. There will be no overall shunting in either direction, although transient small right-to-left and left-to-right shunts occur during each cardiac cycle. Pulmonary and systemic flows, at least at rest, will be equal. On exercise, however, a fall in systemic vascular resistance, with or without an increase in infundibular stenosis, will result in a right-to-left shunt with cyanosis. The systemic flow will then exceed the pulmonary flow. With increasing degrees of obstruction in the subpulmonary right ventricular outflow tract, a dominant right-to-left shunt develops. Cyanosis then becomes a constant feature. Such severe obstruction may be present from birth. More usually, increasing infundibular stenosis develops coincidentally with progressive right ventricular hypertrophy. Cyanosis is dependent on the degree of pulmonary stenosis but is unrelated to the degree of aortic override.

Typically, the mean pulmonary arterial pressure is lower than normal, consequent upon the reduced flow of blood to the lungs. The pulmonary arterial systolic pressure, though lower than that in the right ventricle, may be higher than normal in the group with mild stenosis and increased

pulmonary flow. The right ventricular systolic pressure rises with systemic hypertension, or on administration of pressor agents such as phenylephrine. But it falls in the presence of a vasodilator agent. The right ventricular pressure may also fall, along with aortic pressure, during, or particularly after, exercise when the systemic vascular resistance is decreased. As already indicated, a fall in systemic resistance, with no change in resistance to right ventricular emptying, will result in an increased right-to-left shunt.

Therapeutic Options

In many centres, primary complete correction is now the treatment of choice, almost no matter what the age or size of the patient. Precise timing may depend on the experience of the particular unit; there is a role for interventional catheterisation in some. Otherwise, the medical management of a symptomatic child is devoted principally to preparation for surgery.

Medical Management

When called to a child undergoing a hypercyanotic crisis, the first actions should be to place the child in the knee-chest position and administer oxygen by face mask. If the child is extremely restless, an intravenous line should be inserted, and a small dose of morphine sulphate, at 0.1 mg per kg, may be all that is required to abort the crisis. If this fails, treatment with a β -blocking agent such as propranolol will reduce tachycardia and increase systemic resistance. It may also have an effect to reduce hypercontractility in response to endogenous release of catecholamine, but there is no evidence for a specific effect to reduce infundibular muscular spasm. The drug should be administered intravenously. Half of this should be given rapidly, and the remaining half more slowly over the next few minutes. If this fails to lead to prompt improvement, then arterial blood gases should be assessed. Accompanying metabolic acidosis should be corrected. Intubation and ventilation may be required in extreme cases, and at this stage an intravenous vasoconstrictor, such as phenylephrine, is often effective. Exceptionally, it will be necessary to construct an emergency systemic-to-pulmonary shunt. In any case, the patient should immediately be referred for definitive intervention, with treating orally with propranolol during the interim.

Surgical Management

The symptomatic infant or child requires surgery, and there is little controversy regarding those over a few months of age. For neonates and young infants, some centres continue to offer surgical palliation for that age group, temporising by construction of a systemic-to-pulmonary arterial shunt. In recent years, there has been a resurgence in transcatheter palliation, including balloon dilation and stenting of the right ventricular outflow tract,³² and stenting of the arterial duct. The role of these interventions, usually reserved for the smaller patient or those with additional anomalies, remains uncertain.

Palliative Procedures

It was in patients with tetralogy that Taussig noted that persistent patency of the arterial duct often prevented the onset of cyanosis. From this, together with Blalock,

she developed the idea that it would be beneficial to use the subclavian artery to create an artificial duct. The procedure is traditionally performed on the side opposite to that of the aortic arch. On this side, the subclavian artery arises from the brachiocephalic artery rather than directly from the aorta. Because of this, kinking is less likely to occur at its origin when it is turned down to become a shunt. When the arch is right sided, therefore, a left-sided shunt is normally performed. Nowadays, modification of the classical shunt by placement of interposition grafts has achieved such excellent results, with negligible mortality and adequate patency, that the modified shunt has become the procedure of choice. While several alternatives were used in the 1950s and 1960s, they were never as popular, or consistently effective, as the Blalock-Taussig shunt. The modified version is now frequently performed through a median sternotomy, rather than the classical thoracotomy approach. Following creation of such interposition shunts in small infants, most units choose to treat the patient with heparin in the initial post-operative period, followed by aspirin until the time of corrective surgery. Studies are underway to examine the potential role of more powerful anti-platelet agents. Acute thrombosis of the shunt, nonetheless, is now rare, but remains an important co-morbid feature, in addition to concerns regarding stenosis of the pulmonary artery, potential damage to the recurrent laryngeal or phrenic nerves, and adverse physiologic effects such as increased flow of blood to the lungs, systemic steal syndrome, and so on. For these reasons, the modified Blalock-Taussig shunt is becoming less frequently used.

Definitive Repair

Intracardiac repair involves reconstituting the ventricular septum, and relieving subpulmonary obstruction. The operation is now rarely performed via a large ventriculotomy, with transatrial closure of the septal defect now almost universal. Any ventriculotomy, even when involving a transjunctional incision to relieve obstruction in the subpulmonary outlet, is minimised, given the late results now being observed in survivors of correction as they reach adulthood.

The hypertrophied outlet septum, together with its parietal and septal extensions, is excised as indicated. In the past, the decision as to whether a transjunctional patch would be necessary was often made based on measurements made on pre-operative angiograms to determine the sizes of the pulmonary arteries relative to the aorta. The need for a patch can also be determined during the operation by using Hegar dilators to measure the narrowest part of the pulmonary outflow tract. Free pulmonary incompetence is inevitable when a patch is placed across the ventriculo-pulmonary junction, often considered transannular, although of course the arterial valvar leaflets are not supported in annular fashion. A unicus aortic homograft was inserted by some in attempts to avoid this complication, but no evidence has accrued to show that the late results of this strategy are superior to use of a non-valved patch. The ventricular septal defect is closed using a patch of knitted Dacron, Teflon, or pericardium secured with either continuous or interrupted sutures.

Surgery should, ideally, result in normal right ventricular pressures, absence of any gradient in pressures between the right ventricle and the pulmonary arteries, and a competent

pulmonary valve. Unfortunately, the nature of the subpulmonary obstruction rarely allows this ideal result. The last decade has seen a shift away from the obsession with complete relief of obstruction, towards attempts to preserve the pulmonary valve, even at the expense of a modest degree of residual stenosis. The belief is that this will minimise the adverse late effects of pulmonary incompetence, and retain the integrity of the outflow tract, avoiding late dilation and formation of aneurysms. The success of such an approach, or course, remains to be seen. The timing of definitive repair must be based on the results in the institution offering treatment. While the literature is replete with excellent results, even when performed routinely in the neonatal period, such outcomes are of little relevance to a unit that cannot provide the same level of intra-operative and post-operative care. The experience at the Hospital for Sick Children in Toronto with palliative shunting for tetralogy of Fallot was reviewed for the period between 1990 and 1994. The analysis revealed a relatively high rate of shunt-related complications, and worse overall survival than in patients who had not undergone palliation. Those undergoing palliation who had a shunt placed in the neonatal period experienced more problems with pulmonary arterial distortion and poor pulmonary arterial growth, and required more reinterventions, than did patients palliated at an older age.³³ For that reason, primary definitive repair for those suffering symptoms, even in newborns, is now the rule in Toronto. Exceptions may be made, nonetheless, for those with small pulmonary arteries, for small or premature infants, and for those with additional cardiac or extracardiac anomalies that might significantly modify the outcome. If palliation is to be undertaken, nonetheless, it is done by the transcatheter route.³²

Early Outcomes

The outcomes for corrective surgery continue to evolve and improve. In an earlier period, and excluding the influence of pulmonary atresia, several factors were identified that introduced a significant increment of risk.³⁴ While historical, they remain as interesting discussion points, and retain their validity today. The first feature was the presence of diffusely small pulmonary arteries, the effect of which is to increase the ratio between the peak ventricular pressures subsequent to repair. The detrimental effect of this feature is neutralised by not attempting primary repair when the ratio of the combined diameter of the right and left pulmonary arteries, measured just before their first bifurcation, to that of the descending aorta is less than 1.5 to 1.³⁵

The second factor relates to abnormalities of the pulmonary arteries, such as anomalous origin of one artery, or stenosis of either artery at its origin. These can all be alleviated by appropriate reconstructive procedures. Additional peripheral stenoses can now be dealt with by balloon dilation at later cardiac catheterisation,^{36,37} particularly when using high-pressure balloons.³⁸ The third risk factor is a small pulmonary valvar orifice, producing a high right ventricular pressure subsequent to repair if the obstruction is unrelieved. The necessary relief is usually achieved by insertion of a patch across the ventriculo-pulmonary junction. This, in and of itself, is no longer a risk factor for early mortality, but it is clearly a risk factor for morbidity in the long term. The use of a valved conduit was another factor identified in this earlier experience. This is now almost certainly of historical interest, since few would now place a

conduit in patients with tetralogy and pulmonary stenosis. The exception, of course, might be when there is anomalous origin of the anterior descending artery from the right coronary artery. A transatrial-transpulmonary approach can also be used in this setting, nonetheless, thus avoiding the need for a conduit.

The final risk factor identified in this historical series remains the most contentious, namely age at repair. Both old and young age appeared as incremental risks in the initial analysis. Old age introduced risks for hospital death, poor post-operative exercise capacity, and impaired left ventricular function. Old age at that stage seemed to be more than 5 years, way beyond any contemporary protocol. But how early should primary correction be recommended? In contrast to surgery for ventricular or atrioventricular septal defects, young age had still remained an incremental risk for repair of tetralogy in some earlier series, but certainly not all. For example, one group reported repair of 100 infants with symptomatic tetralogy undergoing surgery consecutively at under 1 year of age with only 3 patients dying.³⁹ Another group corrected 56 infants under 6 months, with 41 undergoing primary repair, and suffered only one death.⁴⁰ Still another group gave details of 30 neonates, 11 with associated pulmonary atresia and 5 with non-confluent pulmonary arteries, and reported no mortality prior to discharge from hospital, albeit with significant late morbidity and mortality.⁴¹ These exceptional surgical results showed what could be achieved, and set the scene for the philosophical change towards definitive repair being performed, at any age, in the symptomatic neonate and infant. There remain, nonetheless, important questions as to what, in the long term, is optimal. For example, in these latter series, over half of the infants required patches across the ventriculo-pulmonary junction. We will discuss the inevitable adverse influence of the resulting pulmonary incompetence below.

Early Post-operative Complications

Problems can occur both in the immediate and late post-operative periods. Apart from the usual complications of cardiac surgery, such as bleeding, a low cardiac output may occur because of inadequate relief of subpulmonary obstruction, or an obstructed or restrictive pulmonary vascular bed. More usually, however, the low cardiac output syndrome occurs in the face of an apparently adequate repair, with preserved ventricular systolic function. In such patients, echocardiographic Doppler studies show evidence of what has now been termed restrictive right ventricular physiology.⁴² There is antegrade diastolic flow in the pulmonary arteries, coinciding with atrial systole throughout the respiratory cycle. As the pulmonary vascular resistance is low, atrial contraction causes flow to be transmitted through a poorly compliant right ventricle into the pulmonary arteries in such a way that, if pulmonary incompetence is present, its duration is shortened (Fig. 36-32). Not only does atrial constriction cause antegrade diastolic flow in the pulmonary arteries, but retrograde flow can also be detected in the superior caval vein, again reflecting a poorly compliant right ventricle.⁴³ The occurrence of restrictive physiology does not appear to be related to age at operation, but is more common on follow-up of patients in whom a patch had been inserted across the ventriculo-pulmonary junction.⁴⁴ Management consists of

Figure 36-32 Doppler echocardiography of pulmonary arterial flow in the early post-operative course following corrective surgery in tetralogy of Fallot shows antegrade flow occurring in diastole coincident with atrial systole, thus shortening the duration of pulmonary regurgitation. This pattern is considered the hallmark of isolated right ventricular restriction. (Reproduced with permission of Dr Seamus Cullen and GMM Publishers, from *The Right Heart in Congenital Heart Disease* edited by Redington et al, 1998.)

maintenance of sinus rhythm and right ventricular preload, keeping the central venous pressure at 12 to 15 mm Hg, early drainage of resulting effusions, and early extubation. If this is not possible, ventilation should be continued using the lowest possible mean pressure in the airways. Careful use of inotropic or inodilator support is required, as these may make things worse and are rarely required, as systolic function is usually preserved. Indeed, a stronger case can be made for the use of vasoconstrictors to maintain pressures of perfusion. Early post-operative restriction is a transient phenomenon, usually resolving within 72 hours, although reappearance in the later postoperative follow-up period may occur.⁴⁴ Paradoxically, if encountered, it is associated with superior functional performance.

Late Outcomes of Intervention

An important paper was published in 1993, which reviewed the late survival and outcomes of surgical repair of tetralogy of Fallot.⁴⁵ Actuarial survival was overall at 86% among patients surviving 30 days after complete repair, compared with 96% in the control population. Further analysis showed rates of survival after 30 years of 90%, 93%, and 91%, in patients undergoing surgery below the age of 5 years, from 5 to 7 years, and at 8 to 11 years, respectively. Of patients who were 12 years or older at the time of operation, only 76% were alive, compared with 93% in controls. Although reflecting a success story, in terms of modification of the natural history of the disease, it became clear, and is increasingly the case, that the late mortality after definitive repair will far exceed the early post-operative risk. Consequently, the last decade or so has seen a shift towards improved understanding of the determinants of late outcomes, with concentration on the adverse effects of pulmonary incompetence, previously considered to be a benign side-effect of relief of the obstructed right ventricular outflow tract.

Physical Response to Correction

Following successful repair, almost all children rapidly catch up in terms of their height and weight. They grow faster than their peers, and height and weight are normal 5 years after repair. Murmurs frequently persist after operation, usually

but not always related to mild residual subpulmonary obstruction, or to acquired pulmonary incompetence. The typical auscultatory findings on follow-up are a single second sound, an ejection systolic murmur in the second or third left intercostal space, and a slightly delayed diastolic decrescendo murmur. If the pulmonary valve has been preserved, the second sound may be split. If subvalvar obstruction is completely relieved without a patch across the ventriculo-pulmonary junction, there may be no murmurs.

Presence of an ejection systolic murmur may complicate assessment of other problems, such as a residual ventricular septal defect, although cross sectional echocardiography with Doppler studies easily allows quantification of residual intracardiac anomalies. In patients who have undergone a staged surgical approach, with a preceding systemic-to-pulmonary anastomosis, reappearance of a continuous systolic-diastolic murmur may be first symptom of a recanalised anastomosis. Those patients have a high risk for acquiring endocarditis, so elective closure in the catheter laboratory is recommended.⁴⁶

Apart from a right aortic arch, when present, the chest radiograph may return to normal, but some will have a bulge over the upper left heart border as a consequence of patching the outflow tract. Cardiomegaly evolves with longer duration of follow-up, and largely reflects right-sided dilation. The electrocardiogram will often show right bundle branch block, with the duration of the QRS complex lengthening in response to dilation of the right heart.

Pulmonary incompetence is found by echo-Doppler examination in between three-fifths and nine-tenths of patients post-operatively. Pulmonary insufficiency is well-tolerated for the first few years, but may result in a chronically dilated right ventricle. Patients with isolated congenital pulmonary regurgitation are known to remain asymptomatic for up to 20 years, but thereafter freedom from symptoms declines rapidly with time.⁴⁷ Symptoms include effort intolerance, right-sided failure, arrhythmias, and sudden death. Chronic pulmonary regurgitation may also adversely affect exercise performance and right ventricular function. One of the difficulties hitherto has been lack of a technique to assess quantitatively the amount of pulmonary regurgitation. By using pressure-volume loops derived from simultaneous intraventricular pressure recordings during angiography, it has now become possible to achieve this goal.⁴⁸ Using this technique, exercise ability using a standard Bruce protocol has been combined with measurements of maximal consumption of oxygen and exchange of metabolic gases using respiratory mass spectrometry.⁴⁹ Maximal heart rate and total duration of exercise were less in those with pulmonary incompetence than in matched controls, and impairment of exercise capacity was shown to be directly related to the degree of pulmonary regurgitation. Those with more severe regurgitation had both reduced exercise performance, and reduced lung compliance. A higher incidence of exercise-induced ventricular arrhythmias was also noted in patients with the most severe pulmonary regurgitation.

Nowadays, pulmonary incompetence can also be measured directly and accurately by cardiac magnetic resonance. Results using this approach have reinforced the earlier data regarding the adverse effects of pulmonary incompetence on functional performance and disturbances of conduction. Before dwelling in more detail on the arrhythmic

problems and their relationship to haemodynamic disturbances, it is of note that, in the long term, the consequences of chronic pulmonary regurgitation may be modified by the diastolic properties of the right ventricle.⁵⁰ Restrictive right ventricular physiology, found in some patients early after operation (see Fig. 36-32), is correlated with beneficial rather than adverse haemodynamic consequences when found on long-term follow-up. Exercise tolerance is enhanced, the heart does not enlarge despite pulmonary regurgitation, and intraventricular conduction disturbances, as reflected by the QRS prolongation, may be less.⁵⁰ In this respect, it should also be noted that the presence of peripheral pulmonary stenosis will increase the amount of pulmonary incompetence following surgery.⁵¹ In the context of the mechanical dysfunction of the right ventricle, it is increasingly appreciated that additional left ventricular dysfunction seems to co-exist in many patients with tetralogy. The right ventricle is anatomically integrated with the left ventricle through subepicardial bundle of aggregated myocytes that run from the free wall of the right ventricle to the anterior wall of the left ventricle. Moreover, the ventricles share the septum, and are enclosed in the same pericardial cavity. The interaction of the two ventricles results in alterations of both diastolic and systolic function.⁵² Experimental work demonstrated that part of the external mechanical work generated by the right ventricle is a direct consequence of left ventricular contraction, or contraction of shared myocytes.⁵³ Patients late after repair show a reasonably strong linear relationship between right and left ventricular ejection fractions.⁵⁴ Left ventricular dysfunction is also known to be a risk factor for sudden death late after repair of tetralogy,⁵⁵ with experimental work showing that acute dilation of the right heart can modify left ventricular performance by a direct effect on load-independent indexes of systolic performance.⁵⁶ Thus, right ventricular dilation may significantly impact on left ventricular systolic function.⁵⁷ In addition, progressive right ventricular enlargement, and worsening right bundle branch block, may result in increasing ventricular dyssynchrony. Indeed, patients with the longest delay between the onsets of contraction of the two ventricles had worse exercise performance, and a higher incidence of ventricular arrhythmia.⁵⁸ Pacing the right ventricle may also improve synchronicity of right ventricular contraction,⁵⁹ and biventricular resynchronisation produces a significant increase in cardiac output.⁵⁷ This method, therefore, may be an effective strategy for patients with biventricular dysfunction who do not respond adequately to replacement of the pulmonary valve. While most attention has been directed towards assessment of problems in the right heart, there are other important late anatomic problems. For example, aortic dilation and valvar incompetence is recognised increasingly with duration of follow-up,⁶⁰ and the risk of endocarditis is significant. Nonetheless, the issues of pulmonary incompetence and the resulting secondary functional and conduction disturbances dominate the clinical picture in most patients.

Post-operative Conduction Disturbances and Arrhythmias

Complete right bundle branch block is frequently produced following surgical correction of tetralogy, and is primarily benign. The duration of the QRS complex in this setting appears to be loosely related to the size of the right ventricle, and in turn, related to the risk of late ventricular

arrhythmia. As such, its documentation and intermittent assessment is important in the late follow-up of these patients.

While heart block can be a cause of death at or soon after surgery, and may cause some late sudden deaths, it is unlikely to account for the majority of deaths. Multiple ventricular premature beats may be a harbinger of more serious ventricular arrhythmias. Ventricular arrhythmias, rather than conduction defects, are more likely to be the basis for sudden death.⁶¹ In this light, the use of ambulatory monitoring has greatly increased the detection of arrhythmias after surgical correction of congenitally malformed hearts, bringing with it many dilemmas in management.⁶²

Disturbances of rhythm, such as frequent unifocal ventricular extrasystoles, more complex couplets, multi-focal extrasystoles, and even asymptomatic non-sustained ventricular tachycardia, were reported in two-fifths or more of patients undergoing 24-hour monitoring on medium-term follow-up.⁶³ Attempts were made in these, and other, series to correlate arrhythmias with residual haemodynamic disorders, such as poorly-relieved subpulmonary obstruction, but the results were conflicting. What has emerged is that frequency of arrhythmias correlates well with age at operation.⁶²

One possible explanation for this finding is the presence with older age of increasing amounts of fibrosis in the right but not the left ventricle.^{64,65} Not only age, but more extensive surgery,⁶⁶ and the extent of the ventriculotomy,⁶⁷ are associated with an increase in ventricular arrhythmias. Whether asymptomatic arrhythmias predict the risk of sudden death is a different matter. Sudden death occurs in about 6% of patients over the long term,⁴⁵ or 4.5 per 100 patients-years,⁶⁸ but can it be predicted? As discussed previously, poor right ventricular systolic or diastolic function, residual subpulmonary obstruction, or a residual ventricular septal defect have been associated with a poor prognosis, possibly owing to arrhythmias. The presence in asymptomatic patients of complex ventricular arrhythmias on 24-hour tape recordings, nonetheless, did not identify a group at risk.⁶⁹

Perhaps the most important recent development in the ability to predict sudden death over the long term in patients with corrected tetralogy of Fallot comes from the establishment of a relationship between QRS prolongation, right ventricular dilation, sustained ventricular arrhythmias, and late sudden death.⁵⁰ Prolongation of the QRS complex of 180 msec or more was shown to predict a 95% probability of near-miss sudden death from sustained ventricular arrhythmias. Conversely, no patient with sustained ventricular tachycardia dying suddenly had a duration less than 180 msec. Prolongation of the QRS complex was associated with right ventricular dilation, and often associated with pulmonary regurgitation, although this was not quantified in the study. When restrictive right ventricular physiology was identified on late follow-up, duration of the QRS complex was always less than 180 msec. In these patients, the right ventricle has a limited end-diastolic volume, since antegrade diastolic pulmonary flow owing to atrial systole limits the amount of pulmonary regurgitation. The myocardial structure that prevents right ventricular dilation even in the presence of pulmonary regurgitation is not currently known, but it appears to be protective in the long term against sudden death and sustained ventricular arrhythmias.

What emerges from these studies is that a mechano-electrical interaction in the right ventricle, namely ventricular dilation and stretch, may underlie ventricular electrical instability. Such mechanisms have already been established for the left ventricle.^{70,71} Of particular interest is that a decrease in right ventricular volume, caused by a Valsalva manoeuvre, can terminate ventricular tachycardia in some patients.⁷² Electrophysiological studies have indicated a re-entry mechanism for sustained ventricular arrhythmias in this setting, which requires areas of slow conduction.⁷³ Further support to the notion that inhomogeneity in depolarisation and repolarisation may form the substrate for malignant ventricular arrhythmias late after repair of tetralogy of Fallot comes from the finding that, in patients with a duration of the QRS complex greater than 180 msec, there are increased dispersions of the QT, QRS, and JT intervals in those with, but not those without, episodes of ventricular tachycardia.⁷⁴

Fragmented electrograms indicative of localised areas of slowed conduction, however, have also been recorded from the inflow region,⁷⁵ the outflow tract,⁷⁶ and throughout the right ventricle in the absence of sustained ventricular tachycardia.⁷⁷ It could be, therefore, that the mechanisms for non-sustained and sustained ventricular arrhythmias are different. This is an important consideration when we consider management of arrhythmias or disorders of conduction during follow-up. It must also not be forgotten that atrial arrhythmias, albeit less dramatic in their effects, are equally as prevalent as ventricular arrhythmia in these patients, and are a significant cause of late morbidity.

Treatment of Arrhythmias and Conduction Disturbances at Follow-Up

The aims of treatment are relief of symptoms and prevention of sudden death. Non-sustained ventricular tachycardia is present in two-fifths or more of asymptomatic patients on follow-up, but the incidence of late sudden death is low, and cannot be predicted from analysis of 24-hour tape recordings. For this reason, routine treatment of asymptomatic patients with non-sustained tachycardia is not currently indicated.⁶² Those with symptomatic ventricular arrhythmia require intervention. If not associated with significant right ventricular remodeling, then insertion of an implantable defibrillator may be indicated.⁷⁸ In many, there will be associated severe pulmonary incompetence, and surgical repair or replacement of the pulmonary valve, often with coincident arrhythmic surgery, and sometimes with insertion of an implantable defibrillator, will usually be performed. Atrial arrhythmias usually respond to medical therapies in the first instance, but increasingly catheter-based ablation of pathways is performed, and is increasingly successful in the early-mid term. Many will also fulfil criteria for surgery to the pulmonary valve, and an additional maze procedure may be indicated.

Treatment of Pulmonary Valvar Incompetence

For years, surgical replacement of the pulmonary valve in symptomatic patients has been the treatment of choice.⁷⁹ When it was shown that right ventricular function did not always recover after valvar replacement, especially if right ventricular ejection fraction was substantially decreased, an earlier intervention was advocated.⁸⁰ This is now one of the most discussed questions in the long-term follow-up of patients with tetralogy of Fallot. Optimal timing of pulmonary valvar replacement is important to preserve right

ventricular function, improve functional performance, and treat impending or symptomatic arrhythmias. The valve needs to be inserted not too late so as to preserve function, yet not too early to avoid the need for early subsequent implantation of a new valve, since the inserted prostheses have a limited lifespan. Timely replacement may protect patients from complications related to pulmonary regurgitation.^{81–84} Following replacement, right ventricular volume usually decreases.⁸⁵ In the case of pronounced right ventricular dilation, especially if serial imaging demonstrates progression, referral for replacement may be indicated before symptoms ensue, although the exact threshold remains to be defined. Several recent studies, nonetheless, suggest that a threshold of right ventricular end-diastolic volume for intervention, in order to preserve the likelihood of adequate reverse remodeling, is in the region of 170 to 200 mL per square meter of body surface area.^{81,86} Thus, serial follow-up of right ventricular volumes, ideally using resonance imaging, is recommended.^{80,81} We predict that the next decade will see a refinement of indications and timing, which rightly or wrongly might be influenced by increasing availability of transcatheter implantation of the pulmonary valve. This new interventional technique was developed by Andersen in Denmark in the early 1990s,⁸⁷ but a combination of technical limitations, and a lack of appreciation of the importance of pulmonary incompetence, conspired to undermine this innovation. The first clinical insertion of a stented valve was reported in 2000.⁸⁸ The percutaneously inserted valve has now been used successfully in patients with conduit from the right ventricle measuring up to 22 mm in diameter.⁸⁹ (see also Chapter 17), but the technique, as yet, is unsuitable for the majority of patients with tetralogy, in whom it is the native outflow tract which is grossly dilated.

In those in whom the valve has been inserted percutaneously, the early to mid-term results are very encouraging. The mortality has been exceptionally low, and the adverse effects, in general, relatively minor. The most common complication is fracture of the stent,⁹⁰ and implantation of a second valve is an effective treatment for early failure.⁹¹ It remains to be seen whether the late results will be robust, but it seems likely that this, and similar technologies, will find an important place in reducing the lifelong need for repeated surgical replacement of the pulmonary valve in these patients.

Other Reinterventions

Reinterventions are necessary in up to one-sixth of patients following reparative surgery over a period of follow-up of 20 years. Patients who require reintervention should be treated by paediatric cardiologists or congenital cardiac surgeons. Surgery may be necessary for residual pulmonary stenosis with right ventricular pressures of two-thirds of systemic. This may involve resection of residual infundibular stenosis, or placement of a patch in the right ventricular outflow tract or across the ventriculo-pulmonary junction. A valved conduit placed from the right ventricular outflow tract to the pulmonary arteries may occasionally be necessary. If there is a large aneurysm involving the outflow tract, excision of the aneurysmally dilated patch, and surgical remodelling by reduction of the size of the right ventricular outflow tract, should be performed to permit an anastomosis with the homograft.⁹² In rare patients with severe tricuspid insufficiency, additional tricuspid valvar

annuloplasty may be required.⁹³ Replacement of the aortic valve, or the aortic root, may be necessary for those with significant aortic valvar regurgitation associated with symptoms, and/or progressive left ventricular enlargement, and/or progressive left ventricular systolic dysfunction, and/or dilation of the root to more than 55 mm in diameter. Closure of a residual ventricular septal defect, by suture or an additional patch, may be indicated if there is a large shunt, in the setting of recurrent endocarditis, or if the patient is undergoing cardiac reoperation for other reasons. Stenosis of the right or left pulmonary artery can usually be managed with balloon dilation and insertion of a stent, thus avoiding or delaying the need for surgery.

RECOMMENDATIONS FOR LONG-TERM FOLLOW-UP

Investigations and Frequency

All patients should have regular follow-up by an appropriately trained cardiologist at least once per year. The investigations include, at a minimum, a thorough clinical assessment, electrocardiogram, echo-Doppler examination to detect and quantify residual pulmonary stenosis and regurgitation, any residual ventricular septal defect, right and left ventricular size and function, aortic regurgitation, and the size of the aortic root.

Investigations are directed toward the known post-operative sequels, and will vary according to the type of operation performed. To document and detect acute changes in right ventricular size and function, as well as to assess pulmonary regurgitant fraction, follow-up should include magnetic resonance imaging at least every two or three years.⁹⁴ Rarely, in some patients, catheterisation may be required, for intervention on the pulmonary arteries, or for coronary angiography in those at risk of coronary atherosclerosis undergoing surgery in later life. The role of arrhythmic surveillance is more controversial. There is minimal evidence showing the value of either Holter monitoring or electrophysiological studies for stratification of risk in those free of clinical symptoms, but they may be useful in defining the type and severity of the arrhythmia in those who complain of undocumented palpitations.

Pregnancy

All patients with tetralogy should have cardiologic counselling prior to conception, and follow-up by an appropriately trained cardiologist during pregnancy. Genetic counselling is also recommended. The risk of recurrence in offspring of parents with tetralogy is 2% if the mother affected, and 1.4% if the father has tetralogy of Fallot.⁹⁵ Assessment of the risk of 22q11 deletion using fluorescent in situ hybridisation is also recommended prior to embarking on a planned pregnancy. The risk of transmission is 50% if one of the parents has such a deletion.

The risk of pregnancy in patients with tetralogy of Fallot after corrective surgery depends on the haemodynamic state. The risk is low, approaching that of the general population, in patients with good underlying haemodynamics. In patients with significant residual obstruction across the right ventricular outflow tract, severe pulmonary regurgitation, tricuspid regurgitation, and right ventricular dysfunction as well as left ventricular dysfunction, the increased

volume load of pregnancy may lead to right heart failure and arrhythmias. In the rare case of right ventricular failure during pregnancy, delivery should be considered prior to term.⁹⁵ Peripartur antibiotic prophylaxis is recommended.

CHAPTER 37

Tetralogy of Fallot with Pulmonary Atresia

EDWARD J. BAKER and ROBERT H. ANDERSON

In this chapter, we deal with one of the most complex, and difficult to treat surgically, of all congenital cardiac malformations. It is still frequent to find the lesion described as pulmonary atresia with ventricular septal defect. Here, we have chosen to call it tetralogy of Fallot with pulmonary atresia. Why should we consider this anomaly part of the spectrum of tetralogy? It is certainly the case that all the patients to be discussed have pulmonary atresia in the setting of a deficient ventricular septum. But other patients with diverse morphologies also have variants of pulmonary atresia with ventricular septal defect, and they will not be discussed. For example, patients with discordant ventriculo-arterial connections as their primary feature, or those with isomeric atrial appendages, or double inlet ventricle, or atrioventricular valvar atresia, can all have pulmonary atresia associated with a hole between the ventricles. In those patients, almost always, the pulmonary arteries are confluent, and are fed by a patent arterial duct. They do not demonstrate the complexity of pulmonary arterial supply that produces the problems encountered so frequently in the setting of systemic-to-pulmonary collateral arteries. We use the heading of tetralogy with pulmonary atresia for this chapter, therefore, because almost without exception, the intracardiac anatomy is that of tetralogy of Fallot when the pulmonary arterial supply is derived from systemic-to-pulmonary collateral arteries.

PREVALENCE AND AETIOLOGY

Because there is no uniformity in how to classify the patients to be described, it is difficult to provide precise incidence for those having tetralogy with pulmonary atresia. Patients with tetralogy of Fallot, considered as a group, made up almost 4% of those with congenitally malformed hearts in the series reported from Liverpool.¹ It is likely that up to one-tenth of these patients will have had pulmonary atresia rather than pulmonary stenosis. In many, the intracardiac anatomy suggests that the pulmonary outflow tract was initially patent, but became atretic during fetal life. In others, particularly in those with systemic-to-pulmonary collateral arteries, the atresia was probably part and parcel of the initial developmental abnormality.² Tetralogy of Fallot with pulmonary atresia is known to be associated with deletions of chromosome 22q11,^{3,4} such deletions also now established as the cause of the velo-cardiofacial syndrome, which typically consists of tetralogy of Fallot along with facial and aural anomalies, cleft palate, and developmental delay.⁵

MORPHOLOGY

Pulmonary atresia exists when there is either complete obstruction, or absence, of the communication normally present between the cavities of the ventricular mass and the pulmonary arteries. In the setting of tetralogy of Fallot (Fig. 37-1), the obstructive form can sometimes be produced

Figure 37-1 The cartoon shows the variants of obstruction within, or absence of, the pulmonary arterial pathways. The left hand drawing shows an imperforate pulmonary valve (yellow arrow), the middle drawing shows muscular obstruction, whilst the right hand drawing shows the solitary arterial trunk.

by an imperforate pulmonary valve. More usually, the blockage of the pathway is muscular, either at the entrance to, or at the distal end of, the subpulmonary infundibulum. The connection is lacking when there is absence of the pulmonary trunk, with the extreme form represented by absence of all the intrapericardial pulmonary arteries. Just as tetralogy of Fallot with pulmonary stenosis can be found with marked variability in intracardiac morphology, so can tetralogy with pulmonary atresia. Before discussing the crucial variations in pulmonary arterial anatomy, therefore, we will discuss the variations in morphology within the heart.

Intracardiac Structure

Significant variations are to be found in the morphology of the ventricular outflow tracts, in the morphology of the interventricular communication, and in the precise connection of the aorta to the ventricular mass, as well as in the associated malformations. Apart from the associated malformations, these features are interrelated. To fulfill the basic diagnosis as tetralogy of Fallot, the aorta must be connected to the ventricles in posterior position relative to the atretic pulmonary outflow tract. The aortic valvar orifice then overrides the crest of the muscular ventricular septum, albeit to varying degree. The phenotypic feature of tetralogy is seen in the structure of the subpulmonary outflow tract, with the muscular outlet septum, or its fibrous remnant, being displaced anteriorly and cephalad relative to the limbs of the septomarginal trabeculation (Fig. 37-2).

Figure 37-2 The specimen shows the phenotypic features of tetralogy of Fallot, in that the deviated outlet septum is attached antero-cephalad relative to the limbs of the septo-marginal trabeculation (yellow Y). In this heart, however, there is muscular subpulmonary (pulm.) atresia, rather than pulmonary stenosis. Note also the muscular postero-inferior (post.-inf.) rim to the interventricular communication.

In a small number of cases, the atresia is found at the mouth of the muscular infundibulum, and the pulmonary valve itself may then be patent. Alternatively, there can be an imperforate pulmonary valve (Fig. 37-3). In the most common pattern, the muscular outlet septum fuses directly with the parietal musculature of the right ventricle, thus obliterating the ventriculo-pulmonary junction. There is then a muscular wall between the cavities of the right ventricle and the pulmonary trunk. Occasionally, the subpulmonary outflow tract is completely absent, so that the leaflets of the aortic valve are attached directly to the parietal ventricular wall (Fig. 37-4). This arrangement is reminiscent of common arterial trunk. In the example shown in Figure 37-4, however, the atretic pulmonary trunk takes its origin from the right ventricular musculature, confirming that the patent arterial trunk is an aorta. Should the intrapericardial pulmonary arteries also be absent, it would be impossible to be sure whether the patent trunk had, initially, been an aorta, and not a common structure. Thus, the arrangement with absence of the pulmonary trunk is best described as a solitary arterial trunk, albeit that clinical presentation is as for tetralogy with pulmonary atresia. In other cases, a fibrous remnant of the outlet septum interposes between the leaflets of the aortic valve and an imperforate pulmonary valve (Fig. 37-5). This arrangement represents tetralogy of Fallot with pulmonary atresia in the setting of a doubly committed and juxta-arterial ventricular septal defect.

The interventricular communication, roofed by the overriding aorta, usually has a fibrous postero-inferior border, made up of continuity between the leaflets of the aortic and tricuspid valves, and often reinforced by

Figure 37-3 In this example, the atresia is produced by an imperforate pulmonary valve. Note again the abnormal insertion of the outlet septum (star) relative to the septo-marginal trabeculation (yellow Y).

Figure 37-4 In this heart, the pulmonary trunk is represented by a fibrous strand, but the strand takes its origin from the right ventricle. The aortic valve is attached directly to the parietal ventricular wall, with no evidence of the subpulmonary infundibulum. The yellow Y shows the septo-marginal trabeculation.

Figure 37-5 In this example, the deviated outlet septum is no more than a fibrous raphe, and there is an imperforate pulmonary valve. This is tetralogy of Fallot with pulmonary atresia in the setting of a doubly committed and juxta-arterial interventricular communication. Note the position of the septo-marginal trabeculation (yellow Y).

a membranous flap. This arrangement makes the defect perimembranous (Fig. 37-6). Cases can also be found, as in tetralogy with pulmonary stenosis, when the postero-inferior limb of the septo-marginal trabeculation fuses with the ventriculo-infundibular fold. In this setting, the defect has exclusively muscular borders when viewed from its right side (see Fig. 37-2). This muscular rim, when present, serves to protect the ventricular conduction tissues, separating them from the crest of the septum. As discussed previously, the defect can also extend to become doubly committed and juxta-arterial (see Fig. 37-5). Such doubly committed defects can themselves extend to become perimembranous, but more usually have a muscular postero-inferior rim. Rarely, the ventricular septal defect may be restrictive, or even completely blocked, due to tissue tags derived from the leaflets of the tricuspid valve. In this latter setting, the overall anatomy of the heart is more like pulmonary atresia with intact ventricular septum, usually with a thick-walled right ventricle and a reduced cavity.

The precise connection of the leaflets of the aortic valve, as in tetralogy with pulmonary stenosis, can vary markedly. In most instances, the leaflets of the aortic valve are connected largely within the left ventricle. Hearts can also be found with predominant, or even total, commitment of the aorta to the right ventricle. This latter combination produces tetralogy of Fallot with pulmonary atresia, but with the ventriculo-arterial connection of double outlet ventricle.

Figure 37-6 In this heart, there is obvious deviation of the outlet septum (star) relative to the septo-marginal trabeculation (yellow Y), with muscular pulmonary atresia, and a perimembranous interventricular communication. Note the fibrous continuity between the leaflets of the aortic and tricuspid (tric.) valves, and the seagull configuration of the pulmonary arteries.

Morphology of the Intrapericardial Pulmonary Arteries

When the pulmonary valve is imperforate, the pulmonary trunk is present, and patent, to the level of the ventriculo-pulmonary junction (see Fig. 37-3). Even in this setting, the trunk itself may supply only one pulmonary artery, the other either having no connection with the pulmonary trunk, or else being completely absent. In many other cases, the pulmonary trunk itself is atretic (see Fig. 37-5). In extreme cases, it is recognisable only as a fibrous strand running between the ventricular outflow tract and the pulmonary arterial confluence, or else joining to one or other of the pulmonary arteries. When the right and left pulmonary arteries are present, usually they are confluent. The confluence itself, usually tethered by either a patent or atretic pulmonary trunk to the ventricular mass, has the characteristic angiographic appearance of a flying seagull. It can vary markedly in size, usually dependent on its source of arterial supply.

The right and left pulmonary arteries can be non-confluent, but one of them usually retains its connection to the remnant of the pulmonary trunk. Non-confluent pulmonary arteries can rarely be found in the absence the pulmonary trunk. Each can then either be supplied by one of bilateral arterial ducts, or one lung can be supplied by systemic-to-pulmonary collateral arteries, with the other fed by a duct through the persisting extrapericardial pulmonary artery. In the most severe examples, the entire intrapericardial arterial tree can be lacking, with supply to the lungs exclusively through systemic-to-pulmonary collateral arteries.

Morphology of Pulmonary Arterial Supply

The final common pathway of pulmonary supply is the capillaries supplying the air sacs of the lungs. These capillaries are connected to an intrapulmonary plexus of arteries, which ramifies within the bronchopulmonary segments. Different parts of the plexus can be supplied with blood from different systemic sources. If all intrapulmonary arteries are connected to unobstructed and confluent intrapericardial pulmonary arteries, the confluence typically supplies all of both lungs, and pulmonary arterial supply is said to be unifocal. When different parts of one lung are supplied from more than one source, the supply is said to be multi-focal.

Unifocal Pulmonary Blood Supply

It is usually the persistently patent arterial duct that provides unifocal pulmonary arterial supply (Fig. 37-7). It is exceedingly rare for confluent pulmonary arteries feeding all of both lungs to be supplied by a solitary systemic-to-pulmonary collateral artery. In rare cases, however, the confluent pulmonary arteries can be fed in unifocal fashion through an aortopulmonary window, or via a fistula from the coronary arteries. In the past, it has also been suggested that the pulmonary arteries can be fed unifocally through a persistent fifth aortic arch.⁶ A fifth arch has never been identified during embryological development, so this explanation seems unlikely. Almost certainly the structures described as the fifth arch represent a malpositioned arterial duct (Fig. 37-8).

Figure 37-7 This image shows the confluent pulmonary arteries in a patient with tetralogy with pulmonary atresia in which the arterial supply is derived through a persistently patent arterial duct.

Figure 37-8 In this specimen, the vessel feeding the pulmonary arteries was initially interpreted as a fifth aortic arch. No such structure, however, exists during embryological development. The vessel is a malpositioned arterial duct. Note that the atresia is produced by an imperforate pulmonary valve, and the pulmonary arteries are of good size.

Multifocal Pulmonary Blood Supply

It is the presence of multifocal pulmonary arterial supply that creates the clinical complexity in tetralogy with pulmonary atresia. The multiple vessels feeding the pulmonary parenchyma are systemic-to-pulmonary collateral arteries (Fig. 37-9). Such arteries hardly ever feed a lung that also receives supply via the arterial duct. It is a useful working rule, therefore, to assume that an arterial duct will not be present when a lung is supplied by systemic-to-pulmonary collateral arteries. Although the systemic-to-pulmonary collateral arteries hardly ever co-exist in the same lung with an arterial duct, they do usually co-exist with confluent

Figure 37-9 The block is photographed from behind in this patient having tetralogy with pulmonary atresia. Note the multiple systemic-to-pulmonary collateral arteries extending from the descending aorta to feed the intrapulmonary arterial tree.

intrapulmonary pulmonary arteries (Fig. 37-10). In such circumstances, the confluent pulmonary arteries are hardly, if ever, connected to all of the bronchopulmonary segments of both lungs. Instead, it is the rule for different arteries to supply different segments of the two lungs. The confluence of intrapericardial pulmonary arteries, itself fed by one or more major systemic-to-pulmonary collateral arteries, is connected to only part of the lungs, while the remainder of the pulmonary parenchyma is supplied directly by a variable number of major systemic-to-pulmonary collateral arteries. These individual collateral arteries feed individual intrapulmonary segments, or groups of segments (Fig. 37-11). They can also communicate with the confluent intrapericardial pulmonary arterial tree (see Fig. 37-10). When both intrapericardial and systemic-to-pulmonary collateral arteries feed different parts of the pulmonary parenchyma, it is essential to determine the proportions supplied by each of the pathways, remembering that in the extreme form of the anomaly, the entirety of both lungs is fed exclusively by systemic-to-pulmonary arteries.

Another variety of multifocal supply is found when the pulmonary arteries are present but non-confluent. The different parts of the lungs may then be supplied by systemic-to-pulmonary collateral arteries, by a duct, by a coronary arterial fistula or aorto-pulmonary window, or by a combination of these. Alternatively, the intrapulmonary arteries may not be supplied either via an arterial duct or by major systemic-to-pulmonary collateral arteries. Blood can then reach them only at precapillary level through acquired collateral arteries. These may either enter the lungs centrifugally through the bronchial arteries, or centripetally via the intercostal or coronary arteries. These acquired collateral arteries can co-exist with the other varieties of arterial supply.

Figure 37-10 The same block as shown in Figure 37-9 is shown from the front. The systemic-to-pulmonary collateral arteries co-exist with good-sized intrapericardial pulmonary arteries. The heart also has a doubly committed interventricular communication, as shown in Figure 37-4.

Figure 37-11 This image, taken from behind, shows a systemic-to-pulmonary collateral artery dividing, with one branch passing in front of (red arrow), and the other behind (green arrow), the oesophagus. The branch passing posteriorly supplies directly a small part of the lung, without anastomosing with the intrapericardial pulmonary arteries.

Major Systemic-to-Pulmonary Collateral Arteries

These arteries are characteristic for the so-called complex variant of tetralogy of Fallot with pulmonary atresia. Their relationship to the bronchial arteries has yet to be fully established. Some of the major collateral arteries have no independent course within the lung parenchyma, extending only from a systemic artery, usually the aorta, to the origin of the intrapulmonary arteries at or near the hilum (Fig. 37-12). Arteries with this morphology are simple conduits. In other circumstances, the collateral arteries extend into the lung along the bronchial tree, branching in the pattern of a bronchial artery, and supplying also the bronchial wall (Fig. 37-13).

A common embryological origin of these vessels with the bronchial arteries cannot be excluded.⁷ It is still recommended, nonetheless, to describe these vessels as systemic-to-pulmonary collateral arteries. The arteries, typically two to six in number, usually arise from the anterior wall of the aorta opposite the origin of the intercostal arteries (see Fig. 37-9). Individual collateral arteries can also take origin from the brachiocephalic arteries, or even from the coronary arteries. When arising from the aorta, the arteries frequently run a retro-oesophageal course (see Fig. 37-11). Usually they can be distinguished from a duct by their histological structure. They can also be distinguished anatomically in most cases, since the arterial duct originates only from a given point within the aortic arch, albeit masquerading sometimes as a purported fifth aortic arch (see Fig. 37-10). Typically, even when branching from a non-dominant aortic arch, the duct originates more or less opposite the take-off of a brachiocephalic or subclavian artery.

Figure 37-12 Another picture of the heart and lungs shown in Figures 37-4, 37-9 and 37-10. This shows the anastomosis at the hilum of the left lung (arrow) between a systemic-to-pulmonary collateral artery and the intrapericardial pulmonary arteries.

Figure 37-13 In this heart-lung preparation, the systemic-to-pulmonary collateral artery highlighted by the yellow arrows branches in concert with the bronchial tree, and is reminiscent of a bronchial artery. The white arrow shows an anastomosis at segmental level between the artery and a branch of the intrapericardial arterial tree.

Characteristic Patterns of Pulmonary Arterial Supply

The potentially complex situation can be simplified by recognition of three major patterns of pulmonary arterial supply. The most favourable arrangement is that in which the right and left pulmonary arteries are confluent, and are supplied by an arterial duct (see Fig. 37-7). With this pattern, the pulmonary arteries themselves are usually distributed in normal fashion to all the bronchopulmonary segments. Such pulmonary arterial supply is unifocal.

In the second major pattern, the intrapericardial pulmonary arteries are confluent, but co-exist with systemic-to-pulmonary collateral arteries (Fig. 37-14). The distribution of the confluent pulmonary arteries themselves is then variable, but hardly ever supplies all the bronchopulmonary segments, with blood passing through the confluence often supplying two-thirds or less of the pulmonary parenchyma. Even in this setting, the ultimate supply to the pulmonary arteries is via the collateral arteries, with anastomoses with the intrapericardial network being possible at hilar, lobar, or segmental levels (Fig. 37-15). The confluence of the pulmonary arteries itself also varies markedly in size, reflecting the number of the bronchopulmonary segments supplied. In this setting, those parts of the lung not supplied by the intrapericardial pulmonary arteries are fed directly by systemic-to-pulmonary collateral arteries, with further variation in the number of arteries present, and the amount of lung supplied by each artery. In most cases, the peripheral supplies of central pulmonary arteries and the collateral arteries do not overlap, but in a proportion of segments two sets of arterial ramifications intermingle (Fig. 37-16).^{7,8}

The third typical pattern of arterial supply (Fig. 37-17) is encountered when there is absence of the intrapericardial pulmonary arteries. In such circumstances, all the bronchopulmonary segments are supplied by multiple

Figure 37-14 The cartoon shows a hypothetical example of multifocal supply. Four collateral arteries are illustrated, shown in red arising from the descending aorta. The right upper artery supplies exclusively the right upper lobe in direct fashion. The right lower artery feeds the middle and lower lobes of the right lung through an anastomosis with the intrapericardial arterial tree, shown in blue, at hilar level (left hand yellow arrow). The left sided collateral arteries are shown feeding the left lung (right hand yellow arrows) through anastomoses at segmental level (see Fig. 37-15). This cartoon takes no cognisance of dual supply (see Fig. 37-16).

Figure 37-15 The cartoon shows the level of anastomoses between the collateral arteries and the intrapericardial pulmonary arteries.

systemic-to-pulmonary collateral arteries. In the presence of systemic-to-pulmonary collateral arteries, therefore, the key to complete clinical diagnosis is to establish the course of each artery, to establish whether it runs directly into the lung or makes connections with intrapericardial and central pulmonary arteries, and to identify with precision the sites of these anastomoses.

Figure 37-16 A part of the lung has been dissected in which the same bronchopulmonary segment is fed both by systemic-to-pulmonary collateral arteries (red) and intrapericardial pulmonary arteries (blue). Note the overlap of the circulations.

Figure 37-17 The cartoon shows the situation in which there is absence of all the intrapericardial pulmonary arteries. The pulmonary parenchyma receives its arterial supply exclusively through systemic-to-pulmonary collateral arteries.

MORPHOGENESIS

Much has been written about the morphogenesis of both the ventricular and pulmonary arterial features of tetralogy of Fallot with pulmonary atresia, albeit derived from speculative embryological concepts, and arguably not improving our understanding. From the stance of ventricular morphology, nonetheless, the anomaly is readily explained in terms of end-stage tetralogy of Fallot, with variation depending upon the specific morphology of the subarterial outlets. Some cases, in contrast, can be interpreted as representing common arterial trunk with absence of the intrapericardial pulmonary arteries, such as those in which a solitary trunk

is connected to the ventricular mass in absence of central pulmonary arteries. This anomaly was initially classified along with other variants of common arterial trunk.⁹ On re-examination of these specimens, doubt was raised as to whether the central pulmonary arteries were indeed absent, or instead were severely hypoplastic.¹⁰ Examples do exist, nonetheless, with unequivocal absence of the intrapericardial pulmonary arteries absent, and with no evidence within the right ventricle of the subpulmonary infundibulum. The argument of common trunk versus tetralogy then depends upon whether the absent pulmonary arteries, had they been present, would have taken origin from an arterial trunk or directly from the right ventricle. The argument is no longer hypothetical, since hearts have now been found with an atretic pulmonary trunk arising from an arterial trunk, showing that the trunk itself had initially been a common structure.¹¹ Experimental studies of rats dosed with bisdiamine have also shown that some fetuses develop classical tetralogy of Fallot, while others exhibit common arterial trunk with pulmonary atresia.² From the standpoint of anatomy, this conundrum is easily resolved simply by describing the ascending great artery found in absence of the pulmonary trunk as a solitary arterial trunk rather than an aorta. Summarising the overall morphogenesis of tetralogy of Fallot with pulmonary atresia, the anatomical prototypes can readily be interpreted, on the basis of morphology, as developing in the setting of typical tetralogy, in the setting of tetralogy with doubly committed ventricular septal defects or, very rarely, in the setting of common arterial trunk.

Embryology has also been invoked to account for the typical patterns of pulmonary arterial supply.¹² Thus, the lungs in tetralogy with pulmonary atresia are supplied either through the confluence of the pulmonary arteries fed by the arterial duct, itself derived from the embryological sixth aortic arch, or else through systemic-to-pulmonary collateral arteries. Initially, it is known that the developing intrapulmonary arterial plexus is connected to the primitive intersegmental arteries, which in turn are connected to the aortic arch system, eventually via the fourth arch.¹³ The concept advanced to explain the arrangement seen in the abnormal hearts is that, when the intrapulmonary plexus eventually achieves its connection to the sixth arch, it loses its connections with the fourth arch and the systemic arterial system. The systemic-to-pulmonary collateral arteries are then explained on the basis of persistence of the primitive intersegmental arteries, some of which also become bronchial arteries. It is argued that these collateral arteries persist only in absence of the duct, which is the critical connection between the structures derived from the sixth arch and the aortic sac. This concept accounts adequately for the majority of cases, and offers an excellent working hypothesis. It is undermined by those occasional instances when systemic-to-pulmonary collateral arteries co-exist with the duct, and both supply the intrapulmonary plexus in the same lung.

In the majority of cases, nonetheless, embryology aids greatly in understanding the complexity of the pulmonary arterial supply. In essence, the intrapulmonary arteries develop along with the lung. They are the final common pathway supplying arterial blood to the pulmonary air sacs. This common pathway can be supplied at the hilum, either by the intrapericardial pulmonary arteries fed through the arterial duct, the derivative of the artery to the sixth

pharyngeal arch, by the rarer sources of unifocal supply, or else by systemic-to-pulmonary collateral arteries, which are primitive intersegmental arteries. These sources of supply can anastomose with different parts of the lungs in the same patient, although usually all the arteries in one lung are supplied either by the duct, or else by the systemic-to-pulmonary collateral arteries. The common pathway can subsequently be further enhanced by acquired collateral arteries, which then reinforce the acinar supply at precapillary level.

PATHOPHYSIOLOGY

The interventricular communication is almost always large and non-restrictive, only rarely being small and obstructive. In a few cases, obstruction may be encountered between the right ventricle and the aorta, producing supra-systemic right ventricular pressures. There is complete mixing of pulmonary and systemic venous blood in the aorta. Hence, distribution of blood to the body as opposed to the lungs depends on the relative resistances offered by the two circulations. The systemic vascular resistance is no different from that in any other cyanotic condition. The complicated pattern of pulmonary arterial supply, however, means that the pulmonary vascular resistance is both complex and variable. Some parts of the lung may be under-perfused and some over-perfused in the same patient. This adds to the difficulties of assessment during life.

Pulmonary Vascular Resistance

The pulmonary vascular resistance results from obstruction at various sites between the aorta and the pulmonary capillaries. These are as follows.

Obstruction at the Aorto-pulmonary Connection

It is rare for there to be a direct connection between the aorta and pulmonary arteries. Examples are an aortopulmonary window along with now rarely performed direct surgical anastomoses. Another direct aortopulmonary connection that can be obstructed, albeit rarely, is a pulmonary artery arising anomalously from the ascending aorta. The connection between the aorta and pulmonary circulations more commonly is a vessel or surgical conduit between the aorta and either the central or intrapulmonary arteries, or the junction between the two. The same principles concerning haemodynamics apply to natural communications, such as a duct or major systemic-to-pulmonary collateral arteries or the rarer coronary-to-pulmonary arterial fistulas, and to surgically created shunts or conduits inserted between the aorta or subclavian arteries and the pulmonary arteries. The difference in pressure between the aorta and the pulmonary arteries is not usually a gradual change in pressure over the whole length of the conduit or vessel. Instead, there is usually an abrupt drop at the pulmonary end. This may be no more than a reflection of the Venturi effect, but there may also be an anatomical obstruction at the pulmonary arterial end of the conduit. This is particularly true in the case of surgical shunts created in early infancy. It is also true of a duct, which tends to become constricted at its pulmonary rather than its aortic end. Localised obstructions and pressure gradients also occur within major systemic-to-pulmonary collateral

arteries. In many cases, these obstructions can become more stenotic with time.¹⁴

Obstruction Within the Pulmonary Arteries

If the central pulmonary arteries lie in the pathway of blood between the aorta and one lung, stenoses may be important, though their inaccessibility makes this difficult to establish. For example, in cases where the entire pulmonary blood flow is derived from a left duct, a stenosis of the central right pulmonary artery would be one factor limiting flow to the right lung. Pressure gradients may also occasionally be demonstrated in intrapulmonary arteries, whether or not these are connected to confluent intrapericardial pulmonary arteries.

Obstruction at Arteriolar Level

Pulmonary vascular disease may develop in parts of the lungs. It can occur in pulmonary segments perfused at high pressure by unobstructed major systemic-to-pulmonary collateral arteries. Changes due to hypoperfusion may also affect pulmonary vascular resistance. In particular, intimal proliferation in an acquired collateral circulation appears to extend into the pulmonary arteries within the acinus, at least in experimental animals.¹⁵ This is likely to raise pulmonary vascular resistance in affected segments.

The combination of all these obstructions is sufficient to reduce the flow of blood to the lungs to below systemic levels in most patients, though a few may show a marked increase in the total pulmonary flow. Since pulmonary and systemic blood becomes completely mixed, systemic arterial hypoxaemia is most severe in patients with a low pulmonary and high systemic flows. Total pulmonary resistance is, therefore, usually high. But this, as outlined above, is the result of obstruction at a number of different levels. From the point of view of surgical repair, what matters is the resistance relative to the vessel to which the right ventricle is to be connected. Normally this is a central pulmonary artery.

When the supply of blood to the lungs is unifocal, all intrapulmonary arteries are connected to a single source of pressure, usually the pulmonary trunk or the confluence between the right and left pulmonary arteries. Under these circumstances, pulmonary vascular resistance can be calculated, provided that mean arterial pressure at that point is known. When pulmonary blood supply is multifocal, in contrast, different intrapulmonary arteries are supplied from different sources. Since the different parts of the lung will then most probably be at different pressures, it is impossible to calculate the overall pulmonary vascular resistance. In fact, all the evidence indicates that regional flow is extremely variable throughout the lungs. Hyperperfused and hypoperfused segments of lungs may be immediately adjacent.

Acquired Collateral Circulation to the Lungs

Collateral arterial supply to the lungs may develop in any cyanotic cardiac condition. These collateral arteries, therefore, can develop in tetralogy with pulmonary atresia, but they are distinct from the major systemic-to-pulmonary collateral arteries that are typical of the condition. From

the pathophysiological point of view, the most important distinction lies in the site of the anastomosis with the pulmonary circulation. Acquired collateral arteries, with rare exceptions, join the pulmonary circulation at immediately precapillary level. Major systemic-to-pulmonary collateral arteries join at the hilum, or at segmental level. Both types of collateral artery provide an effective supply of blood to the lungs. Since acquired collateral circulation never produces cardiac failure, there must be a high resistance to flow between the aorta and the pulmonary arteries.

PRESENTATION

Fetuses with tetralogy and pulmonary atresia can be diagnosed with a high degree of accuracy before birth.¹⁶ The postnatal clinical presentation is almost entirely dependent on the amount of flow to the lungs. If such supply depends on patency of a duct, then patients are liable to present as neonates with severe cyanosis when the duct narrows or closes. Major systemic-to-pulmonary collateral arteries, by comparison, form a relatively stable source of pulmonary arterial supply. In these patients, therefore, the onset of clinically detectable cyanosis may be delayed well beyond the neonatal period. Indeed, of patients with major systemic-to-pulmonary collateral arteries, a small proportion has excessive pulmonary flow, and presents in cardiac failure.

The patients usually present with the combination of cyanosis and exertional dyspnoea. Failure to thrive is often present. Many patients, however, have a balanced flow to the lungs, with few, if any, symptoms and occasionally may demonstrate normal growth. Patients may initially present with non-cardiac clinical features of chromosome 22q11 deletion, such as difficulties with feeding and developmental delay. Occasionally, they may present with evidence of immunodeficiency or hypocalcaemia as part of the picture of the DiGeorge syndrome.

CLINICAL FINDINGS

Most, but by no means all, patients are clinically cyanosed from birth. In the minority with increased flow of blood to the lungs, cyanosis may escape detection until the patient is a few months, or even years, old. Respiration is quiet unless pulmonary flow is excessive. Since there is run-off from the aorta, the peripheral pulses are equal and jerky in proportion to the pulmonary flow. The praecordium is characteristically quiet, since there are no thrills, and the degree of right ventricular hypertension is not usually sufficient to give a right ventricular lift. Only in infants with excessive pulmonary flow is the praecordium active. It may be possible to feel both the ejection click and the second heart sound.

The first heart sound may be followed by a loud aortic ejection click in all but young infants, this being due to the dilation of the aortic root. The second heart sound is single. Blowing and continuous murmurs are frequently audible. A localised continuous murmur may suggest persistent patency of the arterial duct, while widespread continuous murmurs are more characteristic of major systemic-to-pulmonary collateral arteries. There is no systolic ejection murmur such as would arise from infundibular stenosis. The continuous murmurs may obscure the early diastolic murmur of aortic regurgitation that often

develops beyond the age of 8 years or so as a result of dilation of the aortic root or infective endocarditis.

Continuous murmurs may not be heard if the pulmonary flow is too low to generate audible turbulence. This is the case in about half of severely cyanotic newborns with this condition. Such newborns are nearly always duct dependent. Severe pulmonary vascular obstructive disease in older children with unobstructed major systemic-to-pulmonary collateral arteries, however, may also prevent generation of a continuous murmur.

DIAGNOSIS

There is, in general, little difficulty with the diagnosis of tetralogy with pulmonary atresia. In older patients with surgical shunts, nonetheless, it may be impossible to distinguish between congenital and acquired pulmonary atresia. In all cases, other clinical features of the velo-cardiofacial and DiGeorge syndromes should be sought, and chromosomal analysis performed to establish 22q11 deletion.

INVESTIGATIONS

Chest Radiography

The so-called *coeur-en-sabot* heart of tetralogy of Fallot is most often found when there is pulmonary atresia. This is because when hypoplasia of the pulmonary trunk is more severe, the hollowness of the pulmonary bay is more pronounced. A right aortic arch is twice as common as in tetralogy with pulmonary stenosis. These findings occur in almost half of all patients with tetralogy and pulmonary atresia. The lung markings are characteristically uneven in size and hence patchy, abnormal linear shadows indicating the position and course of collateral arteries. The unevenness exists because, in the presence of major systemic-to-pulmonary collateral arteries, some parts of the lung may be under-perfused while others are over-perfused. Furthermore, in older patients, particularly those who have had previous thoracotomies, the extensive acquired collateral circulation may produce rather granular lung fields.

Electrocardiography

The electrocardiogram usually shows right atrial hypertrophy, and almost always right ventricular hypertrophy. This feature easily distinguishes the condition from pulmonary atresia with an intact ventricular septum in newborns, who usually have a conspicuous lack of right ventricular forces. The mean frontal QRS axis is downward and to the right, usually between +100 degrees and +180 degrees.

Echocardiography

The diagnosis of the intracardiac arrangement will be confirmed echocardiographically, but in most cases echocardiography will not be able to demonstrate all aspects of the complex pulmonary arterial supply. Colour Doppler imaging, nonetheless, can exclude significant major collateral arteries in many cases.¹⁷

The parasternal long-axis view shows a large aortic valve overriding the crest of the muscular ventricular septum. The atretic right ventricular outflow tract may be seen in

short-axis parasternal cuts. Hypoplasia of the pulmonary trunk frequently permits the left lung to intrude between it and a transducer placed in praecordial position, thus obscuring the pulmonary valve and trunk. This can be overcome by moving the transducer into a high praecordial, or even suprasternal, position and obtaining a ductal cut. This shows the left pulmonary artery, the pulmonary trunk, and the right ventricular outflow tract in their long axis. The same cut will image a left duct in the presence of a left aortic arch. From these, and subcostal cuts, the origin of the left and the proximal right pulmonary artery may be seen, as may their confluence when it is present.

From the subcostal view, the overriding aorta can be seen when the transducer is depressed and angled anteriorly from the four-chamber view. With clockwise rotation from this point, it is usually possible to demonstrate the blind-ending right ventricular infundibulum when present, and thereby rule out common arterial trunk in most cases. Subcostal imaging can also demonstrate those rare cases in which the pulmonary arterial supply is derived through an aortopulmonary window.

Instances of an imperforate pulmonary valve can often only be differentiated from severe tetralogy by means of Doppler colour flow imaging. In both, the hypoplastic pulmonary trunk continues beyond the dense immobile echo immediately distal to the right ventricular outflow tract, which is either the imperforate or a severely stenotic pulmonary valve.

Suprasternal imaging of the right pulmonary artery is almost always possible when it is present, even if it is hypoplastic, although care must be taken not to confuse this structure with collateral arteries in the mediastinum. In terms of size of the arteries, there is a good correlation between echocardiographic imaging and angiographic investigation, though the lumen imaged echocardiographically is always slightly smaller than the true lumen.¹⁸ Having found the right pulmonary artery, the operator should rotate the transducer while keeping the artery in view so as to demonstrate its continuity with the left pulmonary artery. As continuity is most reproducibly assessed in a single cut, it is a good idea to move the transducer a little down from the suprasternal notch. The confluence will then appear as an inverted V. As the transducer is rotated counterclockwise from suprasterally, a left aortic arch is normally seen. If this does not happen, the counter-clockwise rotation should be continued, for then it is likely that the bifurcation of a left brachiocephalic artery will be seen, indicating the presence of a right aortic arch. The region of the bifurcation should be scanned with colour Doppler imaging to search for an arterial duct. Then the transducer should be returned to its neutral position used for imaging the right pulmonary artery, and then rotated clockwise. If there is indeed a right aortic arch, the round or elliptical section of the aorta seen above the right pulmonary artery will elongate as this rotation occurs, and the tight curve of a right arch will emerge. In the presence of a left arch, similar clockwise rotation will ultimately demonstrate the bifurcation of a right brachiocephalic artery, which should again be scrutinised for a duct.

Suprasternal views will also demonstrate anomalous origin of one pulmonary artery from the ascending aorta, the appearances usually being very similar to those of a

common arterial trunk. The key to the differentiation between common trunk and tetralogy with pulmonary atresia in this situation is the presence of a blind right ventricular outflow tract and pulmonary trunk in those patients with tetralogy. If neither of these is seen, it may be impossible to distinguish echocardiographically between these two conditions in the presence of anomalous origin of one pulmonary artery. Colour Doppler usually allows the origins of major systemic-to-pulmonary collateral arteries to be established. The lungs themselves, however, obscure the intrapulmonary arteries. As a result, it is often not possible to establish the connections between the collateral arteries and the pulmonary arteries. As part of the echocardiographic study, the function of the patent cardiac valves should be studied. In particular, aortic regurgitation must be ruled out in adolescents or adults.

Magnetic Resonance Imaging

Cardiac magnetic resonance imaging with three-dimensional reconstruction is excellent at demonstrating the anatomy of the central pulmonary arteries.¹⁹ It can often demonstrate these arteries when other techniques, including angiography, have failed.²⁰ It can also show the presence and origin of major collateral arteries²¹ (Fig. 37-18). For these reasons, if it is available, it should be used prior to angiography to help in planning invasive studies. Fast imaging combined with breath-holds allows imaging of the peripheral distribution of the pulmonary and major collateral arteries (Fig. 37-19).

Computerised Tomographic Imaging

Where magnetic resonance imaging is not available, contrast computerised tomographic angiography can provide similar anatomical information.²² The exposure to irradiation involved precludes the repeated imaging of the pulmonary vasculature in children with this anomaly, and magnetic resonance imaging is generally preferred.

Cardiac Catheterisation and Angiography

Complete investigation of the pulmonary arterial supply is essential in a patient with tetralogy and pulmonary atresia. It is best undertaken early in life, or as soon after presentation as possible. The intracardiac anatomy is usually clearly shown by echocardiography. The source, or sources, of pulmonary perfusion, and the presence and size of central pulmonary arteries, should be established echocardiographically, by magnetic resonance, computerised tomographic imaging, or by angiography. The details of the distribution of pulmonary perfusion, nonetheless, can often only be ascertained by selective catheterisation and angiography (Figs. 37-20 to 37-22).

It is usually best to make injections of contrast in the upper part of the descending aorta as the first stage of an angiographic investigation. This will demonstrate patency of any normally positioned duct, as well as the origin of the majority of major systemic-to-pulmonary collateral arteries. A similar angiogram can be obtained if a balloon catheter is floated through the heart and aorta to lie in the lower descending thoracic aorta. During transitory occlusion of the aorta with the inflated balloon, contrast

medium is injected through side holes proximal to the balloon.

Angiography in the aortic root is necessary if non-invasive imaging has indicated that there is a more proximal source of pulmonary perfusion, such as a fistula between the coronary and pulmonary arteries, an aortopulmonary window, an anomalous origin of one pulmonary artery, a duct that arises from the brachiocephalic artery, or major collateral arteries arising from the brachiocephalic arteries. Postero-anterior and lateral projections with craniocaudal tilt are preferred. These are particularly helpful in showing small confluent pulmonary arteries, since the craniocaudal angulation elongates the V-shaped confluence in the postero-anterior projection. The craniocaudal tilt will also help separate the anterior pulmonary confluence from more posteriorly placed major systemic-to-pulmonary collateral arteries.

Selective Catheterisation

Selective catheterisation can be achieved in major systemic-to-pulmonary collateral arteries, surgical shunts, and central pulmonary arteries. It is best to enter the central intrapericardial pulmonary arteries whenever possible. This is particularly valuable when the arterial supply to the lungs is unifocal, since pulmonary vascular resistance can then be estimated. Catheters should be passed as far distal into any collateral artery as is possible in order to detect pressure gradients.

Selective angiography should address three questions. First, how does blood reach each part of the lungs? Second, are the central pulmonary arteries and the sources of pulmonary blood supply interconnected? Finally, are there any obstructions to the pulmonary blood flow? Manipulation of catheters from a transvenous route through the heart into the aorta enables most of the necessary selective angiograms to be carried out. It is usually best, nonetheless, to use the retrograde arterial route. Precurved catheters, with end holes so a guidewire can be used, are ideal for this. The long curve of the neck of the catheter keeps the tip pressed against the wall of the aorta, and it is often difficult to avoid entering collateral arteries originating from the descending aorta. The tight curve at the tip is valuable for crossing surgical shunts. In the case of shunts between the subclavian and pulmonary arteries, the tip, once engaged in the shunt, then directs the guidewire down it.

If a central pulmonary artery can be entered, a pulmonary arteriogram is best taken in the right and left anterior oblique projections, since this permits assessment of which segments of the two lungs are connected to the central pulmonary arteries. The disadvantage of frontal and lateral projections in this case is the overlapping between the two lungs in the lateral projection. Injection of contrast medium by hand is usually adequate for demonstration of smaller major systemic-to-pulmonary collateral arteries, but power injections are preferable for larger arteries. Otherwise, the large flow will excessively dilute the contrast medium.

During manipulation to enter major systemic-to-pulmonary collateral arteries originating from the descending aorta, intercostal arteries are frequently entered, particularly when they are enlarged as a result of supplying acquired collateral circulation to the lungs. Entry to

Figure 37-18 These magnetic resonance images, from the same patient, show the morphology of the pulmonary arterial supply. **A**, A three-dimensional rendering from behind. Two large systemic-to-pulmonary collateral arteries are seen emerging from the descending aorta (*arrows*). **B**, A slightly rotated view compared to panel **A** shows two additional major systemic-to-pulmonary collateral arteries arising from the left subclavian artery and the right common carotid artery (*arrows*). The reformatted planar images (**C** and **D**) allow the course of these arteries to be followed. **C**, The collateral artery arises from the left subclavian artery as it descends into the left lung (*arrow*). **D**, A horizontal planar slice demonstrates the presence of hypoplastic, confluent pulmonary arteries (*arrow*).

Figure 37-19 These magnetic resonance images are again from the same patient. As in Figure 37-18A, panel A shows a three-dimensional rendering from behind. In this patient, a large systemic-to-pulmonary collateral artery arises from the descending aorta (*larger arrow*). It passes to the right, and there is a severe narrowing before it enters the vasculature of the upper lobe of the right lung (*smaller arrow*). B, A reformatted planar image of the collateral artery permits the area of narrowing to be examined in greater detail (*arrow*). C, Another systemic-to pulmonary collateral artery, taking its origin from the right subclavian artery (*larger arrow*), extends to supply the lower part of the right lung. Its tortuous course can be followed until it divides to supply a large part of the lung (*smaller arrow*). D, This collateral artery in planar view (*larger arrow*), which shows at the same time the hypoplastic intrapericardial pulmonary arteries (*smaller arrow*).

Figure 37-20 These frames, together with those shown in Figures 37-21 and 37-22, are all from the same patient. They show how it is possible to build up a composite picture of the blood supply to the lungs. Panels A and C are frontal plane projections, while panels B and D are the corresponding lateral projections. The collateral artery shown in C was not present on a previous angiocardigram. It is possible to infer the segmental distribution of the pulmonary arteries, as for example the supply to the right lower lobe as shown in D, by summing the information available in the frontal and lateral projections. Note the obstruction at the end of the shunt in A. The intrapericardial pulmonary arteries are seen as a hairpin configuration in the lateral projection. MAPCA, major aorto-pulmonary collateral arteries.

an intercostal artery may be suspected from the posterior course of the catheter from the aorta toward the paravertebral gutter, in contrast to the anterior course of major systemic-to-pulmonary collateral arteries toward the hilum.

Other varieties of preformed catheters may occasionally prove helpful, for example, coronary arterial catheters when the supply to the lungs, be it acquired or congenital, is derived from the coronary arteries.

Pulmonary Venous Wedge Angiography

With good non-invasive imaging, and selective angiography of the major systemic-to-pulmonary collateral arteries, the anatomy of the pulmonary arteries should have been demonstrated. Only occasionally will it be necessary to use pulmonary venous wedge angiography. Indeed, a pulmonary venous wedge angiogram may fail to demonstrate central pulmonary arteries even when they are present. Either the

pressure in the artery may be too high to permit contrast medium to be forced back to the hilum, or the vessel opacified may not be connected to the central pulmonary artery. Confident exclusion of the presence of central pulmonary arteries may, therefore, require pulmonary venous wedge angiography in several sites (Fig. 37-23).

FEATURES OF SOURCES OF PULMONARY ARTERIAL SUPPLY

Major Systemic-to-Pulmonary Collateral Arteries

The major systemic-to-pulmonary collateral arteries appear as large tortuous arteries, originating usually from the descending aorta, but occasionally from the brachiocephalic arteries and, exceptionally, from coronary arteries. They anastomose with intrapulmonary arteries in the

Figure 37-21 Panels A and B, in frontal and lateral projections, respectively, are selective injections into one of the systemic-to-pulmonary collateral arteries found in the patient illustrated also in Figures 37-20 and 37-22. Note the obstruction in the collateral artery.

Figure 37-22 This selective injection, shown in frontal (A) and lateral (B) projections, was made into another of the major systemic-to-pulmonary collateral arteries found in the patient illustrated in Figures 37-20 and 37-21.

region of the hilum and are never connected to intercostal arteries. They accompany bronchuses, but only rarely form a plexus around them. In essence, they are no different in appearance in the neonatal period from later life.

Arterial Ducts

When a duct originates on the side opposite to the aortic arch, it is likely to arise close to the bifurcation of the brachiocephalic artery and pass to the intrapericardial pulmonary artery on that side, usually taking a straight course, but sometimes showing a wandering track. Rarely, the duct may originate from an anomalous retro-oesophageal subclavian

artery arising as the last branch from the aorta. Exceptionally, bilateral ducts may be present.

Intrapericardial Pulmonary Arteries

Central pulmonary arteries are most easily recognised when they are confluent, as they usually are. The confluent pulmonary arteries, together with the abbreviated pulmonary trunk, appear like a seagull in flight when seen in the frontal projection. This resemblance is heightened by cranio-caudal tilt, this procedure elongating the pulmonary trunk. The confluent central pulmonary arteries appear in the lateral projection like a hairpin, extending anteriorly to the trachea. Where there is doubt as to the identity of an artery

Figure 37-23 The confluence of the intrapericardial pulmonary arteries in this patient is illustrated by means of a pulmonary venous wedge injection. (The original picture was supplied by the late Dr Robert Freedom, Hospital for Sick Children, Toronto, Canada, for the second edition of this book, and was reproduced with his permission.)

in the mediastinum, a particular problem when the central pulmonary arteries are not confluent, the fact that the pulmonary trunk is usually attached to the heart, if only by a fibrous cord, is helpful. Because of this, on a cineangiogram viewed in motion, the intrapericardial pulmonary arteries are seen to move with the heart, whereas other mediastinal arteries move, if at all, with the lungs.

Interconnections Between Major Systemic-to-Pulmonary Collateral Arteries, Central Pulmonary Arteries, and Intrapulmonary Arteries

The intraparenchymal pulmonary arteries in tetralogy with pulmonary atresia are essentially normal. In particular, with rare exceptions, their distribution is that of normal pulmonary arteries. If they are hypoperfused at low pressure, they appear narrow, with deficient peripheral branching. By comparison, if they are hyperperfused, and at high pressure, they appear large and tortuous, with increased background haze. If pulmonary vascular obstructive disease supervenes, the background haze diminishes, but the arteries remain tortuous.

The abnormalities of the intrapulmonary arteries occur mainly at the hilum. Instead of fusing into a single hilar artery, as they normally do, they may remain separate. As a result, the pulmonary arterial supply to an entire lobe, segment, or even part of a segment may be completely isolated from the remainder of the lung. The segmental or lobar arteries can be connected proximally to a central pulmonary artery, to a major systemic-to-pulmonary collateral artery, or to both. The usual result is that supply of blood is compartmentalised, with each major collateral artery being the sole arterial blood supply to part of the lungs. Injection of contrast medium into that artery will then opacify only that region of lung. Occasionally, on viewing a selective injection of contrast medium into a major collateral artery on a moving cineangiogram, wash-out of contrast medium may be seen as a result of non-opacified blood entering the intrapulmonary artery. This may be because more than one major systemic-to-pulmonary collateral artery is supplying the same region of lung, and hence there is a duplicate pulmonary arterial supply. When a surgical shunt has been created to augment

pulmonary arterial supply, and contrast medium is injected into the pulmonary artery by some route other than the shunt, wash-out of contrast medium is to be expected at the point of anastomosis of the shunt to the pulmonary artery.

By combining the information obtained from all the selective injections into major systemic-to-pulmonary collateral arteries, shunts, and intrapericardial pulmonary arteries, it should be possible to determine the supply to each pulmonary segment. Most importantly, it should also be possible to establish how much of the parenchyma of each lung is connected to each pulmonary artery. In making this assessment, it is important to recognise duplicate supply when it exists. For example, if the left upper lobe is connected to a major systemic-to-pulmonary collateral artery and to the central left pulmonary artery, whereas the left lower lobe appears only to be connected to a major systemic-to-pulmonary collateral artery, a shunt into the central left pulmonary artery will, on the face of it, only increase blood supply to the left lower lobe. If careful inspection reveals wash-out from one lobe to the other, then this would increase the supply to the entire left lung.

Obstructions Within the Entire System of Pulmonary Arterial Supply

As has been described, obstructions and stenoses can occur at many levels in the pulmonary circulation. Haemodynamic pressure gradients are sometimes documented at sites where no angiocardigraphic stenosis is seen. Usually, obstructions are angiocardigraphically obvious. Cranio-caudal tilt during injection into a central pulmonary artery increases the likelihood of detection of proximal stenosis of the central right or left pulmonary artery.

Acquired Collateral Arteries

An acquired collateral circulation is a rare finding in the first 3 months of life, but it develops over time, particularly after surgical thoracotomies, when adhesion of the visceral and parietal pleural layers permits the development of centripetal collateral circulation from the chest wall to the lungs. Acquired collateral circulation appears on aortography as myriads of tiny vessels, which may originate from any artery in the thorax. Bronchial arteries are recognised by their relation to the trachea and bronchial tree, and the way in which they form a nutritive plexus in the bronchial walls. The result is that the bronchial tree lights up in the course of the aortogram because of the contrast between the air in the lumen and the contrast medium in the walls.

NATURAL HISTORY

It is difficult to be sure of the natural history of patients having tetralogy with pulmonary atresia, since before cardiac surgery was available, the condition was frequently confused with either tetralogy of Fallot or common arterial trunk. The prognosis without treatment is extremely poor for patients with duct-dependent pulmonary supply. At the other end of the scale, patients with increased, but not excessive, pulmonary arterial supply can survive into the third and fourth decade of life without surgical treatment. Adults with the condition eventually develop left ventricular dysfunction, often compounded by aortic

regurgitation.²³ Systemic arterial saturations of oxygen fall slowly with increasing age. These two examples represent the two ends of the spectrum of prognosis. Overall, the majority of patients with tetralogy of Fallot and pulmonary atresia will not survive more than a few years without surgical treatment.

MANAGEMENT

Neonates with duct-dependent pulmonary blood supply should be treated with parenteral prostaglandins E₁ or E₂ while waiting for surgical palliation. Treatment may be required to combat heart failure for patients with excessive pulmonary blood flow through major systemic-to-pulmonary collateral arteries.

Definitive Repair

When confluent pulmonary arteries are present, definitive repair consists of closing the ventricular septal defect and connecting the right ventricle to the pulmonary trunk or pulmonary arterial confluence. This was first reported by Rastelli and colleagues, who used a valveless conduit.²⁴ The long-term results using aortic or pulmonary homografts are better, as obstruction appears to be rare in this type of conduit. These are now the preferred surgical conduit. If there is continuity between the right ventricle and pulmonary trunk, correction can often be achieved with a patch reconstruction, similar to the technique for tetralogy with pulmonary stenosis.

Results for radical correction in suitable patients were reported some time ago²⁵ with an overall mortality of 14%. Just over half the patients required a valved conduit to restore continuity from the right ventricle to the pulmonary arteries. In the remainder, it proved possible to reconstruct the right ventricular outflow tract with a patch. It was subsequently demonstrated that there was a strong positive correlation between the probability of hospital death and the ratio between the right and left ventricular systolic pressures after bypass.^{26–28} The risk of post-operative death rises steeply if the ratio of these pressures at the end of the repair is equal to or greater than one. The causes of a high ratio are residual gradients in the right ventricular outflow, residual major systemic-to-pulmonary collateral arteries, and hypoplasia and incompleteness of arborisation of the intrapericardial pulmonary arteries. Definitive repair is possible if 15 of the 18 bronchopulmonary segments are connected to confluent pulmonary arteries. Repair can also be achieved if 11 or more segments are connected to the central pulmonary arteries, but when the number is between 11 and 14, there is an increased risk of a high post-operative pressure ratio and an increased surgical mortality.^{29,30} Other risk factors are related to the number of segments fed by the central pulmonary arteries. These are small size of the proximal right and left pulmonary arteries, non-confluent pulmonary arteries, and a high number of systemic-to-pulmonary collateral arteries. There is also some evidence that very young age, or age greater than 8 years, adds to the risk of definitive repair.³⁰ More recent analysis of a large cohort of patients treated over almost 30 years, with around one-third having major systemic-to-pulmonary collateral arteries, showed that results had improved with time, but the number of broncho-pulmonary

segments supplied by the native pulmonary arteries remained a significant determinant of achieving complete repair.³¹

The key to achieving satisfactory results is careful selection of patients, attempting repair only in those who are predicted to have a low probability of severe post-operative right ventricular hypertension. Recent surgical reports have supported this view, with most authors favouring a staged approach to repair. In patients unsuitable for primary repair, palliative procedures are undertaken to encourage growth of hypoplastic pulmonary arteries. Systemic-to-pulmonary collateral arteries are ligated or occluded, or else anastomosed to the central pulmonary arteries.^{32–34}

An alternative approach has been advocated by Reddy and colleagues.³⁵ They argue that systemic-to-pulmonary collateral arteries are not a reliable source of flow of blood to the lungs. The flow may be too high, leading to pulmonary vascular disease, or the collateral artery may become progressively stenosed, leading to distal arterial hypoplasia. Either way, segments of lung may be lost to the pulmonary circulation, and the proportion of patients eventually suitable for definitive repair reduced. They reported their experience of one-stage complete unifocalisation, with repair where possible, in 85 patients ranging in age from 10 days to 37 years. In one-sixth of this cohort, the central pulmonary arteries were absent. Complete unifocalisation with repair was achieved in 56 patients, unifocalisation without closure of the ventricular septal defect in 23, and multi-stage sequential unifocalisation, involving the anastomosis of all the collateral arteries to the central pulmonary arteries or to a central conduit, in 6. The decision to proceed to complete repair with closure of the ventricular septal defect was taken intra-operatively, guided by a study of flow to gauge the resistance of the newly unifocalised pulmonary vascular bed. In those patients in whom it proved possible to achieve complete repair, the pressure post-operatively in the right ventricle was between 25% and 80% of that measured in the left ventricle. There were nine early, and seven late, deaths, these fatalities occurring mostly in younger patients, and those undergoing complete repair. Survival at 4 years was 74%, but three-fifths of the patients required reintervention for residual pulmonary arterial problems in the first 5 years.

Palliative Procedures

Palliative procedures may be necessary to increase, or occasionally to decrease, the flow to the lungs. The long-term goal is definitive repair, so palliative procedures have a dual purpose: first, to improve the management of the immediate clinical problem, and second, to make the patient suitable for definitive surgical repair. Preparation for definitive repair needs to address two problems: enlargement of hypoplastic central pulmonary arteries and unifocalisation of pulmonary perfusion.

Management of Hypoplastic Central Pulmonary Arteries

Early intervention to increase the flow in diminutive central pulmonary arteries has long been advocated. There is good evidence that it can improve the eventual outcome,^{32,33,36}

even though the enlargement achieved may not affect uniformly the entire pulmonary arterial tree. The choice is between a shunt, and reconstruction of the right ventricular outflow tract using a patch or conduit while leaving open the ventricular septal defect. There is no clear consensus about which choice is preferred. There is evidence that early connection of the right ventricle to the pulmonary arteries promotes more pulmonary arterial growth than does a shunt.³⁷ Reconstruction of the right ventricular outflow also has the advantage of allowing direct access to the pulmonary arteries so that interventional procedures can be undertaken to address stenosis of the pulmonary arteries.

Since enlargement of the pulmonary arteries is not uniform, areas of pulmonary arterial stenosis may well remain following palliation. A combined surgical and interventional approach to the pulmonary arteries is now widely advocated. Balloon angioplasty, and the deployment of intravascular stents, are used after reconstruction of the right ventricular outflow tract to promote unobstructed flow to the maximum number of bronchopulmonary segments.^{20,33}

One disadvantage of early reconstruction of the right ventricular outflow tract is that it needs cardiopulmonary bypass, and carries a higher risk than does placement of a shunt. It is also recognised that reconstruction using a patch can lead to stenosis of the pulmonary arteries, especially the left, and that the patch can dilate in aneurysmal fashion. These considerations have led some surgeons to prefer a shunt as an initial procedure.^{27,32} Peripheral shunts have fallen from favour, since they can lead to distortion of the pulmonary arteries. Central shunts, either constructed of a Gore-Tex tube or by disconnecting the pulmonary trunk and anastomosing it end-to-side to the ascending aorta,³⁸ are now preferred.

Unifocalisation

There are two options for dealing with the major systemic-to-pulmonary collateral arteries. The first is to obliterate them, either by surgical ligation or by embolisation using coils, while the second is surgical unifocalisation. If there is a dual blood supply to pulmonary segments, and obliteration is combined with, or follows, construction of a shunt or reconstruction of the right ventricular tract, this combination will encourage flow, and hence growth and development of the central pulmonary arteries. If the collateral artery is the sole supply to an area of lung, ligation has been advocated in the hope that hypoplasia of that region of the lung will result, with compensatory hypertrophy of those regions connected to the central pulmonary arteries. Necrosis of the region of lung supplied by the ligated collateral artery is unlikely, but has been reported in exceptional cases. In practice, this approach has not been successful.

A better approach to collateral arteries that are the sole supply to parts of the lung is surgical unifocalisation. The aim of this approach is to maximise the number of bronchopulmonary segments perfused from the central pulmonary arteries. Technically this is not easy, as the collateral arteries are located posteriorly in the mediastinum, while the pulmonary arteries are anterior. Early results were disappointing, but better results have now been achieved. Depending on the precise anatomy found, a number of

techniques have been used, including direct and prosthetic anastomosis, division of a collateral artery with end-to-side anastomosis of its distal end to a pulmonary artery, and insertion of xenograft pericardial tubes.^{32,34} Such operations rarely achieve unifocalisation at a stroke, since it is often difficult to connect together all intrapulmonary arteries on one side, let alone both. The procedures can be carried out at the same time as construction of a shunt or surgical relief of pulmonary arterial stenosis, but not in combination with reconstruction of the right ventricular outflow tract. Where the central pulmonary arteries are non-confluent, completely absent, or judged to be too hypoplastic to be amenable to the staging approach, an artificial confluence can be created using a prosthetic or xenograft pericardial tube. The confluence is connected to a shunt, and the collateral arteries unifocalised by connection to the confluence.^{34,39,40} Collateral arteries can be embolised with coils after definitive repair, and when there is still a large left-to-right shunt through unligated arteries. It is preferable to embolise such collateral arteries prior to definitive repair if this is undertaken as part of a combined interventional and surgical strategy.^{20,33}

Obstructions in major systemic-to-pulmonary collateral arteries can lead to a progressive reduction in overall pulmonary perfusion, or to hypoperfusion of a significant part of the pulmonary parenchyma. There is little in the literature about balloon angioplasty and stenting of these obstructions as purely palliative measures to improve systemic oxygenation or as a prelude to unifocalisation. The interventional approach may have a limited role in some circumstances, but some of these stenoses cannot be successfully dilated even with high-pressure balloons.⁴¹

Strategies for Management

In this complex and varied condition, generalisations about regimes for treatment are unwise. Each patient requires detailed investigation, and an individual strategy for treatment must be devised by a clinical team that has extensive experience in management. Earlier in this chapter, we identified three characteristic patterns for pulmonary perfusion. These were confluent pulmonary arteries with a unifocal supply, confluent but hypoplastic central pulmonary arteries with major systemic-to-pulmonary collateral arteries, and complete absence of the central pulmonary arteries with the pulmonary perfusion solely from major collateral arteries.

The first of these patterns is the easiest with which to deal. The pulmonary arteries are generally of a good size, and are connected to all of the bronchopulmonary segments. The management is comparable to that for tetralogy of Fallot with pulmonary stenosis. Definitive repair can be carried out as a primary procedure,⁴² or a shunt is constructed in the neonatal period and definitive repair carried out in the first few years of life. The decision between the two will depend upon the size of the pulmonary arteries and the experience of the surgeon.

In patients with hypoplastic pulmonary arteries, it is essential to intervene early in life to encourage growth. This involves either reconstruction of the right ventricular outflow tract, with a patch or valveless conduit, or placement of a central aortopulmonary shunt. Major collateral

arteries that form a dual supply to part of the lung with the central pulmonary arteries are ligated or embolised as part of the same procedure, or more commonly as a second staging procedure. Collateral arteries providing the sole supply to part of the lung are anastomosed to the central pulmonary arteries, ideally directly, but if necessary using a prosthetic graft. The aim is to connect the central pulmonary arterial confluence to as much of the pulmonary parenchyma as possible, and to achieve unobstructed flow of blood. Balloon angioplasty, or stenting, of the pulmonary arteries may be necessary to deal with localised obstructions. Using this approach, approximately half of these patients will eventually have central pulmonary arteries of sufficient size, and supplying sufficient arterial supply to the lungs, to make them suitable for definitive repair.

The third pattern is the most difficult to treat. Operations to create a central pulmonary confluence using grafts have been described.^{34,39,40} The long-term success of this approach, however, is not established. In patients with a stable and well-balanced pulmonary perfusion, conservative management has been advocated, with the eventual aim of offering them transplantation of the heart and lungs.^{30,43}

Results of Surgery

The majority of patients require multiple surgical interventions. Results of individual operations, therefore, are not as important as the results of the overall programme of treatment. The results can be difficult to ascertain from published surgical series. What is clear is that the results are much worse when tetralogy is associated with pulmonary atresia rather than stenosis. The early mortality of definitive repair reported in published series varies between 4% and 15%.^{14,20,27,32,33,34,38} Many patients, despite palliative staging procedures, are never candidates for definitive repair. The proportion of patients that can be converted from being inoperable to operable by staging procedures is difficult to determine from the published series, but overall it seems to be little more than half. The staging procedures themselves carry a significant risk, with a reported mortality of at least 10% in most series. There does seem to be some evidence that the chances of achieving operability from staging operations are improved by starting early in life.³⁶

Recent studies have shown that the mortality for either primary or staged repair has improved,^{35,44,45} but there is limited information about the long-term outcome for survivors of surgery. One large series⁴⁶ showed a significant late mortality and rate of reintervention, while others²⁷

found that there was a low, but constant, risk of dying in survivors of surgery.²⁷ Survival was 82%, 69%, and 58% at 1, 10, and 20 years, respectively. Taking into account the attrition rate before surgery, it is clear that, despite the many advances in recent years, the overall results of treatment for this condition remain disappointing.

Transposition

CANER SALIH, CHRISTIAN BRIZARD, DANIEL J. PENNY, and ROBERT H. ANDERSON

The congenital malformation characterised by origin of the arterial trunks from morphologically inappropriate ventricles has probably been the source of as much confusion and controversy as any other single topic in paediatric cardiology. When Matthew Baillie described the first case,¹ he had no problems with nomenclature, describing the entity in accurate fashion as a singular malformation (Fig. 38-1).

His choice of terminology was echoed in the description of the second case by Mr Langstaff,² albeit that this gentleman did not even give his readers the pleasure of knowing his initials! Since then, the entity most usually described simply as transposition has been defined in many different ways, and has been used to describe many different types of congenital cardiac malformations. The term, however, has not always been employed with the accuracy displayed by Matthew Baillie. Perhaps because of this, the malformation has been the source of several polemics within the

last decades. The arguments have centred on whether the morphological arrangement of the arterial trunks should be defined primarily according to their ventricular origin,³ or on the basis of an anterior location of the aorta relative to the pulmonary trunk.⁴ The disagreements have been non-productive. The problems are readily circumvented by distinguishing between these features, and then by describing both, rather than nominating one in isolation as the basis of diagnosis.⁵ There is little doubt, however, that in the clinical setting it is the origin of the arterial trunks from the ventricles which is paramount. It is this feature that determines the patterns of flow of blood through the heart, irrespective of the relationships of the arterial trunks. It is the combinations of segmental connections that produces the variations still described in terms of transposition. We will describe the combination to be discussed in this chapter simply as transposition, including only those patients having the specific combination of concordant atrioventricular and discordant ventriculo-arterial connections (Fig. 38-2). In this way, we distinguish the group of patients with this particular variant of discordant ventriculo-arterial connections from those associated also with discordant connections at the atrioventricular junction. This second combination is best described as congenitally corrected transposition (see Chapter 39). Both these variants are then distinguished from discordant ventriculo-arterial connections seen in combination with isomeric atrial appendages (described in Chapter 22), and those found with functionally univentricular atrioventricular connections (described in Chapter 31). Relationships of the aorta relative to the pulmonary trunk are described separately as also, when necessary, is the specific infundibular morphology.

Figure 38-1 The illustration used by Matthew Baillie to show the essence of his singular anomaly. Note the anterior and right-sided location of the aorta. The crow quill inserted from the left ventricle passes through the pulmonary trunk, and then through a persistently patent arterial duct so as to emerge in the aorta. The alphabetic notation used by Baillie is as follows: A shows the right atrial, and B the left atrial appendages. C and D are the morphologically right and left ventricles, respectively. E is the cavity of the left atrium, and F is the left pulmonary artery. G shows the persistently patent arterial duct, while H is the aorta arising from the right ventricle. J and K are brachiocephalic arteries, and M shows the pulmonary veins. Baillie seems to have ignored I!

HISTORICAL BACKGROUND

Before we describe the specific morphology of hearts showing the combination of concordant atrioventricular and discordant ventriculo-arterial connections, it is pertinent to review briefly the controversies that underscored the disagreements discussed above. To the best of our knowledge, it was John Farre⁶ who first used the term transposition in the context of a cardiac malformation. He undoubtedly used it to describe the origin of the great arterial trunks from morphologically inappropriate ventricles. Since then, however, there was a period during which it became the norm to define the entity in terms of the anterior location of the aorta.⁷ During this period, it was also considered that the anterior location of the aortic valve should be combined with support from a muscular infundibulum.⁸ If transposition is defined on the basis of an anterior aorta, and this feature

Figure 38-2 The cartoon shows the segmental combinations producing the lesion described as transposition, namely, concordant atrioventricular and discordant ventriculo-arterial connections. As shown, the lesion can exist with either usual atrial arrangement (left hand) or in the mirror-imaged variant (right hand). Note that the aorta is usually left-sided with the mirror-imaged variant. Morph, morphologically.

is then combined with considerations of segmental connections at the atrioventricular and ventriculo-arterial junctions, it is possible to define eight basic patterns in which each arterial trunk arises from its own ventricle (Fig. 38-3).

It is the use of the concept encapsulated in Figure 38-3 that has underscored the use of the qualifier congenitally corrected as frequently applied to transposition. Amongst the variants shown in the figure, some produce physiological correction of the circulatory patterns, such that the systemic venous blood reaches the lungs despite being pumped by the morphologically inappropriate ventricle. In two of these variants, however, there is also anatomical correction, in that the aorta takes its origin from the morphologically left ventricle despite its anterior position. In two of the other variants, the circulations are in parallel rather than in series, despite the fact that the aorta arises in concordant fashion from the morphologically left ventricle. It was the use of corrected in an anatomical sense,

being dependent upon the definition of transposition as an anterior aorta, that produced the potential for confusion. Still further problems arose when it was suggested that the aorta also required to be supported by a muscular infundibulum if it was to be considered corrected in terms of its morphological origin.⁹ In reality, it makes little sense when considering clinical presentation to describe a patient with an anterior aorta arising from the left ventricle as having transposition when the atrioventricular connections are also concordant. Thus, over recent years, there has been an increasing groundswell of opinion in favour of defining transposition on the basis of the origin of the great arterial trunks from morphologically inappropriate ventricles. Such a definition, in addition to removing the confusion of an anterior aorta arising from the left ventricle being considered as transposed when the atrioventricular connections are concordant, also proves its value when considering those rare cases in which the arterial trunks

Figure 38-3 The cartoon shows the eight variations that can be constructed by combining usual and mirror-imaged atrial arrangements (morphologically right atrium in teal, morphologically left atrium in pink); right hand and left hand ventricular topology (morphologically right ventricle with a teal cavity; morphologically left ventricle with a pink cavity), and an anterior right-sided or left-sided aorta (aorta in pink; pulmonary trunk in teal). The upper four panels show the arterial trunks arising in discordant fashion, while they are concordantly connected in the lower four panels. The combinations in blue squares have the circulations in parallel, whilst those shown in red squares have circulations in series. The orange commas show infundibular musculature supporting an arterial valve.

are connected to morphologically inappropriate ventricles, but with the aorta in posterior position, and with fibrous continuity between the leaflets of the aortic and mitral valves.¹⁰ The pattern of arterial relationships and infundibular morphology seen in this setting¹⁰ is the one more usually encountered in the normal heart. Such abnormal hearts, with an aorta located posteriorly and rightward but arising from the morphologically right ventricle, obviously cannot be described as transposition by those who insist upon an anterior position for the aorta as the essential criterion for definition.⁴ Such an approach to nomenclature, based primarily upon relationships of the arterial trunks, can be internally consistent. It is inappropriate, therefore, to insist that the users of an internally consistent system simply abandon it, and adopt another system that may itself have deficiencies. The system that we now use, therefore, is a compromise, basing the use of transposition on the combination of specific atrioventricular and ventriculo-arterial connections. This is also the solution adopted by the International Working Group on Nomenclature, and that advocated by the consensus statement prepared on behalf of the Society of Thoracic Surgeons.¹¹ The approach is based on the paramountcy of segmental connections, but recognises the need also to describe, when appropriate, both arterial relationships and infundibular morphology, albeit using mutually exclusive terms. In this way, all potentials for confusion are avoided.⁵

PREVALENCE AND AETIOLOGY

Although a rare malformation, accounting for only about one-twentieth of all congenital cardiac malformations, transposition was responsible for up to one-fifth of cardiac deaths in infancy prior to the era of surgical correction. Boys are affected two to three times as frequently as girls. Although no definite aetiological factors have been identified, the condition is held to be more frequent in infants of diabetic mothers.¹² Maternal intake of alcohol,¹³ poor nutrition¹⁴ or a stressful life event¹⁵ during pregnancy may increase the risk of transposition in the offspring, while addition of folic acid to the maternal diet may result in a modest reduction in risk.¹⁶

ANATOMY AND MORPHOGENESIS

Anatomy

It is the basic combinations of concordant atrioventricular and discordant ventriculo-arterial connections that produce the entity we call transposition (see Fig. 38-2). The anatomical situation can be complicated by the presence of a ventricular septal defect, an obstruction within the left ventricular outflow tract, both of these malformations, or by other associated malformations.¹⁷ It has become customary, nonetheless, to describe cases as being simple when hearts have an intact interventricular septum and no obstruction of the left ventricular outflow tract, even if they are complicated by other lesions such as persistent patency of the arterial duct.

Basic Segmental Combinations

The essence of transposition is the presence of a morphologically right atrium joined to a morphologically right ventricle that gives rise to the aorta (Fig. 38-4), together with a morphologically left atrium connected to a

Figure 38-4 The morphologically right ventricle in this heart, connected by the tricuspid valve to the morphologically right atrium, supports the aorta above a muscular infundibulum. This, together with the arrangement shown in Figure 38-5, is the essence of transposition, in this case with an intact ventricular septum.

morphologically left ventricle that supports the pulmonary trunk (Fig. 38-5).

This combination of connections can be found with either usual or mirror-imaged atrial arrangements (see Fig. 38-2). It cannot exist when there is isomerism of the atrial appendages. Hearts with isomeric atrial appendages can, of course, have biventricular atrioventricular connections, right hand topology, and discordant ventriculo-arterial connections. Such hearts are closely related to transposition as it is defined for the purposes of this chapter, but those with isomeric atrial appendages have grossly abnormal venoatrial connections as their major feature (see Chapter 22).

The internal anatomy of the atriums is basically normal, although most frequently the oval foramen is patent, or there is a deficiency of the floor of the oval fossa. Even if the flap valve overlaps the rim of the oval fossa, it is flimsy and can be ruptured easily by balloon septostomy. In keeping with this normal atrial anatomy, the sinus and atrioventricular nodes are in their anticipated position. There are no histologically specialised tracts of conduction tissue between the nodes. This is not to deny the importance of the prominent muscle bundles in the right atrium in conduction of the sinus impulse. These bundles, such as the terminal crest or the superior rim of the oval fossa, are, however, composed of ordinary working myocardium.

Unlike the atrial chambers, ventricular morphology is subtly different from normal. The ventricular septum is much straighter than usual, not showing the multiple curves so typical of the normal heart. The pulmonary valve

Figure 38-5 The other half of the heart shown in Figure 38-4. The morphologically left ventricle, connected to the morphologically left atrium through a mitral valve, gives rise to the pulmonary trunk. Note the fibrous continuity between the leaflets of the pulmonary and mitral valves.

Figure 38-6 This heart is from a patient with mirror-imaged atrial appendages. The star shows the right-sided morphologically left appendage. There is left hand ventricular topology, with the morphologically right ventricle being left-sided, and discordant ventriculo-arterial connections. As is usual for this combination, the anterior aorta is left-sided.

is not wedged as deeply between the mitral and tricuspid valves as is the aortic valve in the normal heart. This, in turn, means that the area of off-setting of the leaflets of the atrioventricular valves is much less marked, as is the area occupied by the membranous septum. Indeed, in over half the hearts with intact septum, it is not possible to find a fibrous component of the ventricular septum. Another consequence of this abnormal arrangement is that the ratio of the dimensions of the inlet and outlet components of the ventricular mass are abnormal in favour of the outlet dimension, although not to the extent seen in atrioventricular septal defects (see Chapter 27). At birth, the walls of the morphologically left ventricular wall are marginally thicker than those of the right ventricle. The right ventricular mural thickness then rapidly increases in the first 2 years of life, becoming much thicker than that of the left ventricle.

The most obvious external abnormality is the relationship of the aorta to the pulmonary trunk. In the majority of patients with an intact ventricular septum, the aortic root is to the right of the pulmonary trunk in hearts in the setting of usual atrial arrangement (see Fig. 38-4), and to the left in the mirror-imaged variant (Fig. 38-6). This is by no means the rule, and patients are found with usual atrial arrangement and intact ventricular septum when the aorta is to the left (Fig. 38-7). Rarely, the aorta may be right-sided and posterior (Fig. 38-8), even when the ventricular septum is intact.

Infundibular Morphology

When the ventricular septum is intact, the aorta almost always has a complete muscular infundibulum, while the leaflets of the pulmonary valve are in fibrous continuity

Figure 38-7 In this patient, the atrioventricular connections are concordant with usual atrial arrangement. The star shows the right-sided morphologically right atrial appendage. The discordantly connected aorta is to the left of the pulmonary trunk. The image has been reoriented so as to show the heart in attitudinally appropriate fashion. (Courtesy of Dr Benson R. Wilcox, University of North Carolina, Chapel Hill.)

Figure 38-8 In this heart from a patient with usual atrial arrangement, concordant atrioventricular connections, and discordant ventriculo-arterial connections, the aorta is posterior and to the right of the pulmonary trunk. There is also fibrous continuity between the leaflets of the aortic and mitral valves in the roof of a co-existing ventricular septal defect.

with the mitral valve (see Figs. 38-4 and 38-5). Variations in this infundibular morphology, for example, the presence of bilaterally complete muscular infundibulums, are not seen nearly as frequently when the ventricular septum is intact as when there is a ventricular septal defect.

Coronary Arteries

Whenever the position of the aortic root is abnormal, the origins of the coronary arteries deviate from those found in the normal heart. The arteries, however, continue to arise from one or the other, or both, of those aortic sinuses that face, or are adjacent to, the pulmonary trunk (Fig. 38-9). The epicardial course of the arteries arising from these adjacent sinuses is much less predictable. Attempts to account for all these patterns in alphabetic fashion, or even worse,

Figure 38-9 The heart was prepared by removing the atrial chambers and the arterial trunks, and is photographed from the atrial aspect. Note the anterior and right-sided location of the discordantly connected aorta. As is always the case in transposition, the coronary arteries arise from the aortic sinuses adjacent to the pulmonary trunk, in this instance with one coronary artery arising from each sinus.

alpha-numeric fashion, have led either to systems that do not account for all patterns,¹⁸ or else to truly formidable codifications that placed immense demands on the memory.¹⁹ When describing the coronary arterial arrangement, therefore, it is best to use a descriptive approach, accounting separately for the origins of the three major coronary arteries from the aortic sinuses, describing their course relative to the vascular pedicle, noting any intramural course, with attention paid to the location of the artery supplying the sinus node.²⁰

Although the coronary arteries always arise from one or both of the aortic sinuses which are adjacent to the pulmonary trunk, the position of these sinuses in space can vary according to the relationship of the arterial trunks (Fig. 38-10). To account for this variability, it is necessary to have a system of description that is independent of spatial relationships. This can be achieved by considering the aortic sinuses as they would be visualised, figuratively speaking, by an observer standing in the non-adjacent aortic sinus and looking towards the pulmonary trunk (see Fig. 38-10). The sinuses supporting the coronary arteries are then located to the right and left hands of the observer. The sinus to the right hand has now become universally known as sinus 1, while that to the left hand is distinguished as sinus 2.²¹ All patterns are then accounted for according to whether the right, circumflex, and anterior interventricular arteries arise from sinus 1 or from sinus 2.²⁰ The system accounts for any and all departures from the normal situation

Figure 38-10 The cartoon shows the potential variability of the aorta relative to the pulmonary trunk in congenitally malformed hearts. With this degree of variability, it is not possible to account for the location of the aortic sinuses in terms of right or left, or anterior or posterior, coordinates without describing each heart separately. Always, however, the coronary arteries arise from the sinuses closest to the pulmonary trunk, and always these sinuses can be distinguished as being to the right hand of the observer standing in the non-adjacent sinus and looking towards the pulmonary trunk, this sinus distinguished as sinus 1, or to the left hand, this sinus then named sinus 2.

Figure 38-11 The cartoon shows the usual arrangement of the coronary arteries in patients with transposition, found in two-thirds of cases. The right coronary artery (red) arises from sinus 2, while the main stem of the left coronary artery (green) arises from sinus 1 before branching into the circumflex (blue) and anterior interventricular (purple) arteries. All variations are described simply by accounting for origin of the three arteries from either sinus 1 (pink) or sinus 2 (yellow), irrespective of the relationship of the arterial trunks themselves. (Original cartoon prepared by Dr Francois Lacour-Gayet, Children's Hospital, Denver, Colorado, and modified and reproduced with permission.)

anticipated for transposition (Fig. 38-11), abnormalities in origins of the coronary arteries in the past representing one of the major risk factors during the arterial switch procedure.

When considering the sinusal origin of the major coronary arteries, it is also necessary to note their radial, vertical, and tangential origin relative to the sinuses themselves. Most usually, the arteries arise within the sinus or at the level of the sinotubular junction, albeit usually eccentrically placed within the sinus. Significant problems can be created for the surgeon during the arterial switch procedure when the arteries take a high origin above the sinotubular junction, or if they have tangential origin through the aortic wall, crossing the attachments of the valvar leaflets at the junction (Fig. 38-12).

These arrangements are associated with an initial course of the artery running obliquely through the aortic wall, so-called intramural origin.²² In addition to sinusal origin, epicardial course is also important, in particular retropulmonary or antero-aortic position of any of the three major coronary arteries.²⁰ The artery to the sinus node is of further significance. It can arise from the initial course of either the right or the circumflex coronary arteries, or it can take a direct origin from one or other of the facing aortic sinuses. Its most important variation, however, is when it crosses the lateral margin of the right atrial appendage (Fig. 38-13). In such lateral position, it is at surgical risk during a standard atriotomy.

Figure 38-12 The cartoon shows an intramural origin of the left coronary artery (compare with Fig. 38-11). At first sight, the arrangement seems the usual one. Closer inspection shows that the main stem of the left coronary artery extends across the zone of apposition of the aortic valve leaflets, and takes its origin from sinus 2, which also gives rise to the right coronary artery. Colourings as for Figure 38-11. (Original cartoon prepared by Dr Francois Lacour-Gayet, Children's Hospital, Denver, Colorado, and modified and reproduced with permission.)

Figure 38-13 In this heart, the artery to the sinus node arises from the right coronary artery, and crosses the atrial appendage to reach the node located in the terminal groove. It was transected by the standard atriotomy. SCV, superior caval vein.

Ventricular Septal Defect

The most significant, and frequently occurring, associated lesion in complete transposition is a ventricular septal defect.¹⁷ As with isolated defects, these may be small, large

Figure 38-14 As with interventricular communications in the otherwise normal heart, those in patients with transposition can be characterised as being muscular, perimembranous, or doubly committed.

or multiple, and they can be located within any part of the ventricular septum (Fig. 38-14). The most characteristic defects are those that open beneath the ventricular outlets, with the muscular outlet septum being malaligned relative to the rest of the ventricular septum, and located within the right ventricle (Fig. 38-15).

Such defects, which occupy a subpulmonary position when seen from the left ventricle, may have a muscular postero-inferior rim, as shown in Figure 38-15, or may extend to become perimembranous. Frequently, such defects are crossed by the tension apparatus of the tricuspid valve, which often inserts to a papillary muscle arising from the outlet septum. The superior and inferior margins, formed by

the outlet and apical components of the muscular septum, diverge towards the parietal wall of the right ventricle. The outlet septum can also be malaligned into the left ventricle. This then narrows the left ventricular outflow tract, producing pulmonary stenosis in association with overriding and biventricular connection of the aortic valve (Fig. 38-16).

In the more common malalignment defects as shown in Figure 38-15, in which the outlet septum is positioned within the right ventricle, it is the pulmonary valve that overrides the septum. With ever greater degrees of overriding, and increasing connection of the leaflets of the pulmonary valve within the right ventricle, a spectrum of anomalies is seen culminating in double outlet from the right ventricle with subpulmonary ventricular septal defect. This whole series is often called the Taussig–Bing complex. We divide the series at its midpoint, including only those with less than half the circumference of the overriding pulmonary valve connected within the right ventricle as examples of discordant ventriculo-arterial connections.

Equally significant from the surgical standpoint are those defects that extend to open to the inlet of the right ventricle. These are hidden beneath the septal leaflet of the tricuspid valve, complicating their surgical repair. When the defect extends to open into the right ventricular inlet, there is the potential for straddling and overriding of the tricuspid valve. In this setting, the muscular ventricular septum no longer extends to the crux, and the atrioventricular conduction axis takes origin from an anomalous postero-inferior atrioventricular node (see Chapter 33).

Apart from in the presence of overriding of the tricuspid valve, the conduction tissue is carried on the left ventricular aspect of the septum, and the postero-caudal rim of the defect is most vulnerable during surgical correction. As with isolated defects, the conduction axis is better protected when the posterior limb of the septomarginal trabeculation fuses with the ventriculo-infundibular fold. Should a muscular defect open to the inlet, however, the axis of conduction tissue will be found in antero-cephalad position.

Other types of defect can be found, such as multiple muscular defects, solitary apical muscular defects, or doubly committed defects roofed by the conjoined leaflets of

Figure 38-15 There is a malalignment defect between the outlet septum and the septomarginal trabeculation (yellow Y). Note the muscular postero-inferior rim to the defect (star).

Figure 38-16 In this heart, the outlet septum is malaligned posteriorly into the left ventricle, and obstructs the subpulmonary outflow tract. VSD, ventricular septal defect.

the aortic and pulmonary valves. They are less common. The aorta is also occasionally found posteriorly and to the right in the presence of a ventricular septal defect. With this arrangement, there is usually aortic-mitral valvar continuity through the roof of the defect. Bilateral infundibulums are also seen more frequently in association with a defective ventricular septum, again most frequently when the arterial trunks are side by side. Other anomalies are also more frequent in association with ventricular septal defect, including juxtaposition of the atrial appendages, aortic stenosis, and aortic coarctation.

Obstruction of the Left Ventricular Outflow Tract

Any lesions that produce obstruction to the outflow tract of the morphologically left ventricle, and which in the normal heart produce aortic obstruction, will produce subpulmonary obstruction in the setting of transposition.¹⁷ Such lesions can be found at valvar or subvalvar level (Fig. 38-17).

Isolated valvar obstruction is rare, being more common in combination with subvalvar obstruction, which may be dynamic, fixed or both. Dynamic obstruction is produced by bulging of the ventricular septum. In its most severe form, this is reminiscent of hypertrophic obstructive cardiomyopathy. When septal bulging itself is less severe, obstruction of the left ventricular outflow tract is frequently exacerbated by a fibrous ridge located on the septal bulge. This can progress to form a complete subvalvar shelf, the ridge extending onto the facing surface of the mitral valvar leaflet (Fig. 38-18). The extent of fibrous stenosis can also be more elongated, giving a tunnel lesion. Other rarer forms of stenosis are produced by anomalous attachment of the tension apparatus of the mitral valve across the outflow tract, or by aneurysms of fibrous tissue tags bulging into the outflow tract (Fig. 38-19). All can exist with an intact ventricular septum, or in association with a ventricular septal defect. When there is a septal defect, however, there is another most significant type of stenosis, namely, malalignment and deviation of the muscular outlet septum into the left

Figure 38-18 In this heart, a fibrous shelf extends from the septum onto the leaflet of the mitral valve. The extent of fibrous stenosis can also be more elongated, giving a tunnel lesion.

ventricle that narrows the subpulmonary outflow tract in association with overriding of the aortic valve (see Fig. 38-16). Most of these fixed stenoses present major problems in surgical removal, either because of their own intrinsic morphology, for example a papillary muscle, or because of their proximity to vital structures, such as the left ventricular conduction tissues or the left coronary artery in the transverse sinus. If removal is attempted, the safest area for resection is the area occupied by the muscular outlet septum.

Associated Malformations

Other malformations can co-exist either when the ventricular septum is intact, or in association with a ventricular septal defect or obstruction of the left ventricular outflow

Figure 38-17 The substrates producing subpulmonary stenosis in transposition are the same as those that produce subaortic stenosis when the ventriculo-arterial connections are concordant.

Figure 38-19 A tissue tag originating from the tricuspid valve in the right ventricle has herniated through a co-existing ventricular septal defect to produce subpulmonary obstruction.

Figure 38-20 These frontal sections are from a wild-type mouse (left hand panel) and a *Pitx2* knock-out mouse (right hand panel) at comparable stages of development. They illustrate the markedly different orientation of the cushions in the developing outflow tract. The knock-out mice proceed to develop either discordant ventriculo-arterial connections or double outlet right ventricle with subpulmonary interventricular communication. (Courtesy of Professor Nigel Brown, St George's Medical University, London, United Kingdom.)

tract. Persistent patency of the arterial duct is particularly significant because it loads the left ventricle, producing a thicker wall. Other significant anomalies are infrequent, but can occur. They include stenosis of the subaortic outflow tract, aortic coarctation, or anomalous pulmonary venous connections.

Morphogenesis

The morphogenesis of transposition is almost as contentious as the definition itself. There are two basic concepts. The first suggests that the anomaly is the consequence of inappropriate separation of the arterial pole of the heart. As a result, the sixth aortic arches, destined to supply the pulmonary arteries, are connected to the morphologically left ventricle, while the fourth aortic arches take their origin from the morphologically right ventricle, the process occurring because the ridges septating the arterial segment of the heart tube fuse in straight rather than in their normal spiral fashion.²³ The second theory puts the seat of maldevelopment not in the arterial trunks, but in the ventricular outflow tracts. This hypothesis suggests that, rather than the subaortic outflow portion of the right ventricle becoming connected to the left ventricle, as occurs in normal development, it is the subpulmonary outflow component, together with the pulmonary trunk, which is thus connected. This concept was first proposed by Keith,²⁴ who invoked differential absorption of the infundibular structures as the causative mechanism. The concept was revitalised under the guise of differential conal growth.³ It now seems that, to explain all the known variants of transposition, including the arrangement in which the aorta arises posteriorly and to the right, it is necessary to invoke maldevelopment within both the outflow tracts and the arterial segment.²⁵ The elucidation of the various theories will require more detailed studies of experimental animal models, such as the Perlecan knock-out mouse.²⁶ Initial evidence from other animal models showing discordant ventriculo-arterial connections, such as the *Pitx2* knock-out mouse, do reveal an abnormal location of the outflow cushions during early development (Fig. 38-20).

PATHOPHYSIOLOGY

Circulatory Physiology

The predominant physiological abnormality in transposition is that the systemic venous return is recirculated to the body via the right ventricle and the aorta, whilst the pulmonary venous return is recirculated to the lungs via the left ventricle and pulmonary trunk. Thus, whereas in the normal heart the systemic and pulmonary circulations are in series, in transposition they function as two separate and parallel circuits. In the fetus, this arrangement results in more desaturation of the upper body than is usual, but is not associated with other significant circulatory instability. After birth, the oxygenated pulmonary venous blood does not reach the systemic circuit, and the systemic venous return does not circulate to the lungs. This results in severe systemic arterial desaturation. In the absence of any communication between the pulmonary and systemic circulations, this is incompatible with life.

In infants, early neonatal survival depends upon persistence of the arterial duct, and an interatrial communication. The arterial duct allows blood to flow from the aorta to the pulmonary vascular bed and increases left atrial filling. Patency of the oval foramen, or a native atrial septal defect, permits mixing at atrial level. During this period, the total flow to the lungs is the sum of the effective and the recirculated pulmonary flows. Likewise, the total systemic flow is the sum of the effective and the recirculated systemic flows. A less obvious, but important, consequence of the separation of the two circulations is that the absolute flows in the systemic and pulmonary circuits may differ markedly one from the other (Fig. 38-21).

Determinants of Systemic Arterial Oxygenation and Mixing

When the ventricular septum is intact, the level of systemic arterial saturation is determined by the effective systemic flow, which is proportionate to the degree of circulatory mixing. The dynamics of intercirculatory mixing are complex.

Figure 38-21 Saturations (left hand panel) and flows (right hand panel) within the heart of a patient with transposition of the great arteries and atrial mixing. Effective pulmonary ($Q_{p, \text{Eff.}}$) and systemic ($Q_{s, \text{Eff.}}$) flows are equal (1 L/min/m²), resulting from the bidirectional shunt at atrial level. However, total systemic (2.4 L/min/m²) and total pulmonary (9.6 L/min/m²) differ considerably such that the pulmonary-to-systemic ratio is 4 to 1. Ao, aorta; CV, caval veins; LA, left atrium; LV, left ventricle; PT, pulmonary trunk; PV, pulmonary veins; RA, right atrium; RV, right ventricle.

The magnitude of the atrial shunt is primarily determined by size of the interatrial communication, the volume and compliance of the atriums and ventricles, and the resistances of the systemic and pulmonary vascular beds. A low-resistance pulmonary circuit combined with a compliant left ventricle results in right-to-left interatrial shunting during ventricular diastole. This leads to increased flow of blood through the left heart to the lungs, which in turn increases pulmonary venous return to the left atrium, and left-to-right interatrial shunting during ventricular systole.²⁷ Conversely, a poorly compliant left ventricle results in reduced right-to-left shunting during diastole, decreased pulmonary flow, and less left-to-right shunting in systole. As a result, the effective systemic flow is reduced, and the arterial saturation is lower.

At the level of the arterial duct, the direction of shunting largely depends upon the pulmonary vascular resistance, and is also determined by the interatrial communication. If the pulmonary vascular resistance is low, and the interatrial communication is non-restrictive, then the ductal shunt is from aorta to the pulmonary arteries, and predominantly from left to right atrium. If the pulmonary resistance is elevated such that the pulmonary arterial pressure exceeds the pressure in the aorta, then the ductal shunt may be reversed, from the pulmonary arteries to the aorta. This results in an important clinical observation whereby the post-ductal blood is more highly saturated than preductal blood. This life-threatening situation is commonly associated with a restrictive interatrial communication, and requires urgent decompression with an atrial septostomy.

Ventricular Septal Defect

The presence of a ventricular septal defect can have a variable influence on the circulation. This in part depends on the size of the defect, as well as on the presence of interatrial mixing, and the pulmonary vascular resistance. A large interventricular communication may provide good

circulatory mixing, but as for infants with concordant ventriculo-arterial connections, the presence of unrestricted flow to the lungs may result in symptomatic heart failure. If surgery is not performed during infancy, then this can predispose to early pulmonary vascular disease, which is generally evident by 6 to 12 months of age.^{28–30} The presence of additional pulmonary, or subpulmonary obstruction, modifies these relationships, and may limit the flow of blood to the lungs. These infants are generally asymptomatic, having a protected pulmonary circulation, adequate mixing, and a well-trained left ventricle.

Growth and Development during Fetal Life and Infancy

Most newborns with transposition are of normal birth weight.³¹ They have been noted to have smaller occipito-frontal circumferences at birth than controls, which may reflect the abnormal haemodynamics and relative desaturation during fetal development of the blood circulating to the brain and upper body.^{32,33} Their growth tends to be restricted in the early post-operative period, but this is followed by an acceleration so that the majority of children have caught up with their unaffected peers by 2 years of age.³⁴

CLINICAL DIAGNOSIS

Presentation

The rates of detection prior to birth are variable, and are discussed elsewhere. If made, antenatal diagnosis allows clinicians to assess the full anatomy in detail, with particular attention to the interatrial communication. The clinical team are then able to organise delivery of the infant in a specialist centre, with immediate postnatal initiation of prostaglandins to maintain ductal patency. Moreover, this enables early transfer to a cardiac centre for full assessment and further intervention with a septostomy. Prenatal diagnosis, therefore, facilitates pre-emptive care and offers early therapeutic intervention, with the intention of preventing haemodynamic instability.

Infants without an antenatal diagnosis present with cyanosis, with or without clinical evidence of circulatory insufficiency. The state of the circulation itself depends on the extent of mixing at ductal and intracardiac levels. In the extreme, some infants may present shortly after birth with cyanosis and circulatory collapse, which is most often related to restriction of the interatrial communication. This situation requires definitive management with an urgent balloon atrial septostomy.³⁵ Infants with a widely patent arterial duct, and a large unrestrictive ventricular septal defect, may present with only minimal cyanosis, but symptomatic pulmonary over-circulation.

Clinical examination during infancy reveals a variable degree of cyanosis, which is unresponsive to inspired oxygen. The adequacy of the peripheral pulses generally reflects the overall circulatory state. Infants with real or pending circulatory collapse will tend to be profoundly desaturated, with globally reduced peripheral perfusion and weak pulses. The presence of pulses in the legs of reduced volume should alert the clinician to an associated coarctation or interruption of the aorta. Cardiac auscultation typically reveals a single second heart sound, and there may also be an audible continuous murmur from the arterial duct, or a systolic murmur related to a ventricular septal defect.

Chest Radiography

The chest radiograph may be unremarkable or abnormal. Cardiac size is often normal, while the pulmonary vascular markings may be reduced, normal, or increased reflecting the volume of flow to the lungs or a restrictive interatrial communication. In around one-third of neonates, the mediastinum is narrow, reflecting the antero-posterior relationship of the arterial trunks.

Electrocardiography

In most newborns, the electrocardiogram is normal. During early infancy prior to surgical intervention, the electrocardiogram may begin to reflect right ventricular hypertrophy, and later demonstrate right-axis deviation. A superior axis in the neonatal period suggests associated abnormalities of the tricuspid valve, particularly straddling or overriding.

Fetal Echocardiography

Significant progress has been made in the screening of fetuses for cardiac malformations.^{36,37} The efficacy of fetal screening is based on the premise that high rates of detection will provide opportunities for parental choice, along with optimal neonatal care and pre-operative management. An improvement in mortality and morbidity for neonates diagnosed prenatally as having transposition has already been demonstrated,³⁵ albeit largely related to improved survival prior to surgical intervention subsequent to antenatal diagnosis rather than to any impact on surgical outcome.³⁵ Nowadays, the patients at highest risk are those with a restrictive interatrial communication, and prenatal diagnosis does not have an impact on this important factor.

Rates of antenatal detection of transposition are very variable, and clearly suboptimal in some regions.³⁸ In mothers referred for comprehensive fetal echocardiography performed by specialist sonographers, the lesion can be detected with high levels of accuracy (Fig. 38-22). A systematic segmental approach is recommended, just as for postnatal studies.³⁹ Regular and detailed assessment of the adequacy of intracardiac mixing, particular at the atrial level, is also useful. Although such restriction at atrial level is a highly

Figure 38-22 Fetal echocardiogram, demonstrating the origin of the aorta (Ao) from the anterior right ventricle (RV) and the pulmonary trunk (PT) from the left ventricle (LV).

specific predictor of the need for emergency neonatal care, its sensitivity is too low to permit detection in all fetuses.⁴⁰ Of recent interest is the advent of four-dimensional fetal echocardiography.⁴¹ A particular advantage of this technique may be that it provides an en face view of the four cardiac valves, thus enhancing definition of the spatial relationships of the great arteries and, in turn, the likelihood of abnormal distribution of the coronary arteries.⁴²

Postnatal Echocardiography

Echocardiography of the neonate with transposition requires confirmation of the basic diagnosis, along with a full assessment of the cardiac anatomy, including the adequacy of intracardiac and ductal mixing, and the likely ability of the left ventricle to support the systemic circulation. The echocardiographic confirmation requires demonstration of concordant atrioventricular and discordant ventriculo-arterial connections. The diagnosis may be suggested by the parallel relationship of the great vessels, but cannot be based on these alone, as this arrangement is also seen in other congenital cardiac malformations, including

Figure 38-23 Cross sectional images obtained from a subcostal window in a patient with transposition. Anterior angulation demonstrates the bifurcating pulmonary trunk (PT) arising from the left ventricle (LV; left hand panel). Further angulation demonstrates the aorta arising from the right ventricle (RV; right hand panel). In this patient, the aortic valve is anterior and to the right of the pulmonary valve.

Figure 38-24 Cross sectional image obtained from a high parasternal window, demonstrating the antero-posterior relationship of the aortic (AoV) and pulmonary (Pul.V) valves.

double outlet right ventricle, or double inlet ventricle with discordant ventriculo-arterial connections.

The atrioventricular connections can readily be determined using subcostal and apical four-chamber cuts. Anterior angulation then confirms the discordant ventriculo-arterial connections. Specifically, the bifurcating pulmonary trunk can be demonstrated originating from the morphologically left ventricle, and the aorta, which is usually anterior, from the morphologically right ventricle (Fig. 38-23). Parasternal imaging reveals the relationships of the arterial trunks. Typically, the aortic valve is positioned anterior and to the right of the pulmonary valve (Fig. 38-24). Parasternal imaging will also reveal the characteristic appearances of juxtaposed atrial appendages (Fig. 38-25).

Additional subxiphoid, apical, and parasternal views, combined with the use of colour Doppler interrogation, should be used to confirm or exclude ventricular septal defects, and demonstrate the direction of associated shunting. The left ventricular outflow tract should always be carefully examined to exclude any obstruction, and the

Figure 38-25 Image obtained from a parasternal window in a patient with left juxtaposition of the atrial appendages. The right atrial appendage (outlined by arrows) is seen interposed between the pulmonary trunk (PT) and left atrium (LA). MV, mitral valve.

atrioventricular valves should be assessed carefully to identify any abnormal attachments of the tendinous cords. Detailed examination of the pulmonary valve and the sub pulmonary region are an essential part of the pre-operative assessment, as any significant obstruction to the left ventricular outflow may influence surgical management.

Detailed echocardiographic assessment of the origin and course of the coronary arteries should routinely be performed prior to surgical intervention.^{43,44} This requires subcostal views of the outflow tract, as well as parasternal short-axis views of the arterial trunks (Fig. 38-26). The aortic arch should always be assessed in detail in order to exclude coarctation or interruption. As it is difficult to exclude coarctation in the presence of a widely patent arterial duct, further echocardiograms should be performed to reassess the arch after prostaglandin is discontinued.

The atrial septum, and flow between the atriums, are best visualised in the subcostal four-chamber view. Deviation of the atrial septum towards the right atrium, with a reduction in the colour flow signal, and increased velocity on pulsed wave Doppler, should immediately suggest the presence of restriction at the interatrial communication. Patency of the arterial duct, and the direction of ductal shunting, should also be confirmed. These features are best visualised from the suprasternal view.

Figure 38-26 Images obtained from a subcostal window demonstrating the coronary arteries. Anterior angulation demonstrates the course of the circumflex artery (circ.; left hand panel). Further angulation demonstrates the right (Rt.) and left anterior interventricular arteries (LAI) originating from a common origin.

Figure 38-27 Angiocardiograms revealing discordant ventriculoarterial connections in a patient with complete transposition. (Courtesy of Dr B.L. Soto, University of Alabama, Birmingham.)

Cardiac Catheterisation

Cardiac catheterisation is no longer routinely performed; all necessary anatomical information should be obtained from cross sectional echocardiography. There is still an occasional role for cardiac catheterisation in the assessment of the pulmonary vascular resistance (Fig. 38-27) of patients in whom there is a clinical suspicion of pulmonary vascular disease. The course and distribution of the coronary arteries can be demonstrated by angiography, particularly when using the laid-back view,⁴⁵ although the important features will usually have been visualised with echocardiography.

Magnetic Resonance Imaging

Pre-operative magnetic resonance imaging may provide useful complementary information in the assessment of the anatomy (Fig. 38-28). It is particularly useful in the assessment of the mass of the left ventricle in the infant presenting late (Fig. 38-29). This may assist involved clinicians in assessing the suitability of an individual patient for an arterial switch operation. Post-operative magnetic

resonance imaging after the arterial switch operation provides excellent assessment of the reconstructed arterial trunks (Fig. 38-30), and can also be used to image the origins of the reimplanted coronary arteries (Fig. 38-31). In the patient after an atrial redirection procedure, in whom conversion to an anatomical repair is being contemplated, magnetic resonance imaging can provide detailed assessment of the function of both the systemic morphologically right ventricle and the morphologically left ventricle.⁴⁶

MEDICAL MANAGEMENT OF NEONATES

Postnatal Stabilisation

The most recent report from the Congenital Heart Surgeons Society identified a mortality rate of 2.5% prior to the arterial switch operation.⁴⁷ Even higher rates have been described.^{35,48} This important pre-operative mortality, in a congenital cardiac malformation which is now associated with excellent post-operative survival, underpins the importance of fetal diagnosis and targeted perinatal care. Neonates diagnosed antenatally should ideally be delivered in a high-risk obstetric unit, with rapid access to cardiac care.⁴² Venous access should be obtained immediately after delivery, and an intravenous infusion of prostaglandin E should then be commenced. Patients with severe acidosis or hypoxaemia may require an immediate balloon atrial septostomy.³⁵ In others, septostomy is generally performed if there is inadequate intracardiac mixing, and significant cyanosis. At our institution, the presence of adequate intracardiac mixing, be it native or after septostomy, is the usual indication to discontinue prostaglandin.

Atrial Septostomy

Following its introduction by Rashkind and Miller in 1966,⁴⁹ atrial septostomy has become well accepted in pre-operative management. The procedure requires passage of a balloon-tipped catheter from the right to left atrium, crossing the oval foramen. The balloon is then inflated with saline and, with a quick, short motion, is pulled into the right atrium. While a femoral venous

Figure 38-28 Magnetic resonance image in a patient with left juxtaposition of the atrial appendages. The aorta (Ao) can be seen arising from the anterior surface of the heart. The right atrial appendage (RAA) can be seen crossing to the left and is superior to the left appendage (LAA).

Figure 38-29 Magnetic resonance angiogram in a 9-month-old patient who presented from a developing country with an intact ventricular septum. The aorta (Ao) can be seen arising from the right ventricle (RV) and the pulmonary trunk (PT) from the left ventricle (LV).

approach was routine, it is now common to use the umbilical vein to enter the heart through the venous duct. Fluoroscopic screening was previously used to guide the procedure (Fig. 38-32), but has largely been replaced by cross sectional echocardiography (Fig. 38-33). This provides a simple and reliable method for monitoring the position of the balloon, as well as assessing the success of the septostomy. It also allows the procedure to be performed, if required, on the intensive care unit. Recently, the routine use of septostomy has come under scrutiny following the observation, in one institutional series, of an association between septostomy and abnormal findings on pre-operative cranial magnetic resonance studies.⁵⁰ These observations have provoked caution in the application of septostomy although their significance will be a matter for debate and further investigation in the future.

Figure 38-30 Magnetic resonance image from a patient after the arterial switch operation. The relationships between the great vessels can be easily identified. The pulmonary arteries (RPA and LPA) straddle the aorta (Ao), typical of the Lecompte manoeuvre. The pulmonary arteries are widely patent.

SURGICAL MANAGEMENT

Historical Perspective

Some of the earliest procedures described for prospective surgical treatment were aimed at achieving anatomical correction. Considering the hurdles existing at the time, which included limited pre-operative assessment of ventricular function and imaging of the coronary arteries, inadequate microvascular surgical techniques, and primitive cardiopulmonary bypass circuits, it is hardly surprising that these attempts were uniformly fatal. Furthermore, many babies with poor intracardiac mixing tended to be extremely unwell at the time of surgery. Even with the advent of the palliative surgical atrial septectomy, morbidity and mortality remained significant.⁵¹ The improved survival in infancy after surgical intervention can largely be ascribed to the advent of the balloon atrial septostomy. This relatively simple procedure, which did not require sternotomy or opening of the pericardium, provided rapid circulatory stabilisation, and afforded a relatively uncomplicated period of growth and nutrition prior to definitive surgery.

Figure 38-32 Images obtained by fluoroscopy in a patient undergoing an atrial septostomy. While the balloon is clearly visible, its precise relationships with important structures including the mitral valve and the pulmonary veins are difficult to discern.

Atrial Redirection Procedures

The ability to achieve stabilisation of the patient by means of the atrial septostomy before surgery set the scene for important surgical advances in the early 1970s. Atrial redirection surgery, however, provided physiological correction, in contrast to the anatomical correction more recently offered by the arterial switch operation. Nowadays, therefore, the Mustard and Senning procedures are rarely, if ever, performed as primary procedures, and will only be briefly discussed here.^{52–55} Their greatest relevance in current practise relates to the significant population of adolescents and young adults that are developing late complications, such as baffle obstruction, arrhythmias, ventricular dysfunction, and end-stage heart failure.

Mustard and Senning Procedures

These procedures involve removal of the atrial septum, and redirection of the systemic venous pathways to the sub pulmonary morphologically left ventricle, and pulmonary

venous blood to the systemic morphologically right ventricle. In the Senning operation, the rerouting of systemic venous blood was achieved by means of infolding of the atrial walls, whereas in the Mustard operation this was achieved using synthetic or pericardial tissue. One of the most popular modifications of the Mustard operation involved creation of a trouser-shaped baffle, with the legs anastomosed to the superior and inferior caval venous inflows.⁵⁶ By the 1980s, such atrial redirection procedures were associated with early post-operative survival exceeding 95%.⁵⁷

Arterial Switch Operation

An important impediment to the earlier success of anatomical correction was the requirement also to relocate the coronary arteries, which in turn demanded advanced microvascular techniques, unavailable at those times. The advent of coronary arterial surgery in adults in the late 1960s changed the potential scope of surgery for neonates with transposition. Alongside these new techniques in adults, coronary arterial translocation, and hence anatomical correction, became a realistic possibility for affected infants. The first successful arterial switch operation was reported by Jatene and colleagues in 1975,⁵⁸ in an older infant with an associated ventricular septal defect. Others around the world quickly followed suit, and within a matter of months there were reports of similar successes.

It became clear rapidly that an important determinant of early outcome was the condition of the morphologically left ventricle prior to surgery, which determined its ability to support the systemic circulation afterwards. Hence the introduction of two-stage repair for patients with a deconditioned left ventricle, with banding of the pulmonary trunk and, if required, placement of a systemic-to-pulmonary arterial shunt. These first-stage procedures trained the left ventricle, permitting the arterial switch itself to be performed some months later.⁵⁹

Another important modification to the arterial switch was then introduced in 1981. This procedure, known as the Lecompte manoeuvre, involved the forward looping of the bifurcation of the pulmonary arteries over the divided aorta, leaving the neo-aorta lying posteriorly. Following the manoeuvre, the pulmonary trunk itself was positioned anteriorly, and could be anastomosed to the original aortic root without creating anatomical distortion.⁶⁰ This procedure is

Figure 38-33 Images obtained during an atrial septostomy using echocardiography. The balloon can be seen inflated within the left atrium (LA), and its relationship to the mitral valve (MV) can be seen (left hand panel). After the balloon is pulled across the atrial septum, its location in the right atrium (RA) can be seen (right hand panel). LV, left ventricle.

still incorporated by most surgeons performing the arterial switch operation. During the first decade of anatomical correction, the pioneers of the arterial switch undertook the operation in infants with associated ventricular septal defects, which were generally beyond the early neonatal period. The first report of successful correction of a neonate with an intact ventricular septum appeared in 1984.⁶¹

The procedure as currently performed involves the transection of the aorta and the pulmonary trunk. The coronary arteries are then detached from the aorta, along with a cuff of aortic tissue, and transferred to the proximal end of the divided pulmonary trunk, thus forming the new aortic root, or the neo-aorta. The defects in the original aortic root left subsequent to detachment of the coronary arteries are repaired with pericardium. The distal end of the divided aorta is then anastomosed to the neo-aorta, thereby connecting the morphologically left ventricle to the systemic circulation. The Lecompte manoeuvre is performed, and the anastomosis of the pulmonary outflow tract is completed (Fig. 38-34).

The arterial switch is now the procedure of choice for almost all neonates. In the current era, the overall mortality is very low, although the early surgical experience demonstrated a significant learning curve.⁶² Whereas, in earlier reports, additional anatomical factors, such as a ventricular septal defect, the coronary arterial pattern, or obstruction within the aortic arch, had an impact on mortality, more recent reports have shown that these effects have decreased over time.^{63,64}

Timing of the Arterial Switch Operation

In most newborns diagnosed in timely fashion with an intact ventricular septum, the arterial switch is undertaken towards the end of the first week of life. The principal

reason for carrying out surgery early in the neonatal period in such infants is to avoid the deconditioning of the morphologically left ventricle. The left ventricular mass begins to regress within a few days of birth, and if this continues, the left ventricle gradually loses its ability to support the systemic circulation subsequent to the arterial switch. Deconditioning may be arrested, or slowed, by the presence of a ventricular septal defect, a large patent arterial duct, or obstruction to the left ventricular outflow tract.

The interval beyond which a primary arterial switch operation cannot safely be undertaken is ill defined. A multi-institutional study carried out by the Congenital Heart Surgeons Society in 1988 suggested that, for neonates with an intact interventricular septum, and without any native pulmonary obstruction, this interval was only 14 days.⁶⁵ No more than one decade later, it has been shown that primary repair can be undertaken at up to 2 months of age without increased mortality, irrespective of the pre-operative echocardiographic appearance.⁶⁶ In recent years, the arterial switch has been reported in infants at even up to 6 months of age, but this account highlighted the potential need for temporary mechanical support in these patients considered to be at high risk.⁶⁷

While our readiness to perform the arterial switch as a primary procedure beyond the first 2 weeks of life has increased substantially over the past decade, our ability to assess the state of the morphologically left ventricle in the pre-operative setting remains limited. The position of the interventricular septum as determined echocardiographically has traditionally been used to assess the readiness of the left ventricle to support the systemic circulation (Fig. 38-35). The compression of the ventricle to a banana shape, however, was shown not to be predictive of the duration of post-operative ventilation, the subsequent need for extracorporeal support, or mortality in patients undergoing an arterial switch operation at greater than 3 weeks of age.⁶⁷ Several quantitative criteria have subsequently been proposed to identify the patient in whom training of the left ventricle may be required, though none appear

Figure 38-34 The cartoon shows the typical postoperative appearance as seen by the surgeon after completion of the arterial switch operation.

Figure 38-35 Echocardiographic image from a patient with an intact ventricular septum. The ventricular septum can be seen bulging into the left ventricle (LV). The patient was aged 9 months at the time of presentation to a specialist centre. RV, right ventricle.

to be robust. These include a left ventricular end-diastolic volume of less than 90% of predicted, a left ventricular ejection fraction of less than 0.5, a left ventricular mural thickness at end-diastole of less than 4 mm, a predicted left ventricular mural stress of less than 120×10^3 dynes/cm²,⁶⁸ a left ventricular mass of less than 60% of predicted⁶⁹ or, when indexed to the surface area of the body, of less than 35 G/m².⁷⁰

Ventricular Training

An important determinant of the likely success of the arterial switch operation for an individual patient is the potential for the left ventricle to support the systemic circulation. When first introduced, the two-stage approach involved an interval of between 5 and 8 months between the stages. It has since become clear that the immature ventricle has the capacity for rapid hypertrophy,⁷¹ and adequate preparation can instead be achieved within days. Thus, the group at Boston Children's Hospital developed the rapid two-stage approach, in which the arterial switch itself was performed within one week of banding.⁷² This strategy, nonetheless, carries significant risks, including volume overload of the right ventricle secondary to the shunt, and an acute increase in impedance to the left ventricle. Taken together, these may contribute to a significant risk of a ventricular dysfunction, and a state of low cardiac output in the early period after banding.^{73,74} In the longer term, abnormal function of the left ventricle, associated with reduced myocardial contractility,⁷⁵ and unexplained increases in ventricular volume, have also been observed after the two-stage procedure.^{76,77}

Considering the potential hazards of preparatory banding, and the ability of the left ventricle rapidly to become conditioned, our institutional preference for patients deemed to be at high risk is to undertake the arterial switch as the primary procedure, with the elective use of a left ventricular assist device immediately after cardiopulmonary bypass.⁷⁸

Coronary Arterial Anatomy

Almost a decade before the arterial switch became routine, Yacoub and Radley-Smith¹⁸ described their classification of the most common coronary arterial patterns, as well as methods for their transfer. Once the arterial switch had become routine in Melbourne, Brawn and Mee described a variety of techniques for coronary arterial transfer in those patients with more complex arrangements.⁷⁹ In an analysis of the outcomes for a large cohort, it was shown that an arrangement in which one or both of the major coronary arteries passed between the arterial trunks was associated with an increased risk of mortality.⁸⁰ An extensive multi-institutional analysis undertaken by the Congenital Heart Surgeons Society has been reviewed on a regular basis. Although earlier reviews^{65,81} suggested that the arrangement of the coronary arteries did not impact on outcome, in retrospect, the relatively high overall mortality at this time may have masked the subtle contribution of coronary arterial anatomy. In a later analysis,⁸² which included more than 500 patients, the anatomy of the coronary arteries was shown to be a risk factor. In this series, there were a number of arrangements which were associated with reduced survival. These included the main stem of the left coronary artery, the left anterior interventricular or the circumflex artery arising from sinus 2, or the presence of an intramural coronary

Figure 38-36 Intra-operative image demonstrating an anomaly of the coronary arteries. The right coronary artery (RCA) and left anterior interventricular artery (LAI) can be seen to share a common origin. The right coronary artery sweeps anterior to the arterial pedicle.

artery. A recent meta-analysis,⁸³ which included almost 2000 patients, showed that mortality for those with any variant coronary arterial pattern (Fig. 38-36) was almost twice that seen in patients with the usual pattern. In this review, a single origin of the coronary arteries, and intramural patterns, were associated with death.

Surgery for Complex Transposition

Transposition with a Ventricular Septal Defect

The presence of a ventricular septal defect was previously an important risk factor for increased surgical mortality, although this is less so in the current era. Thus, in a review of European centres, the mortality for the arterial switch in the presence of a ventricular septal defect was found to be 13%, compared to 3% when the ventricular septum was intact. The presence of the interventricular communication was found to be significant on univariate but not on multivariate analysis.⁶⁴ Similarly, in a recent review of the experience in Michigan,⁶³ it was observed that the presence of a ventricular septal defect did not affect the outcome for the arterial switch operation.

Surgery in Infants with Significant Pulmonary Hypertension

Pulmonary vascular disease develops rapidly in the presence of a ventricular septal defect, or when an arterial duct is sufficiently large to cause pulmonary hypertension. When pulmonary vascular disease is established, patients are no longer candidates for corrective surgery. As a guide, a pulmonary vascular resistance of greater than 8 Wood units is considered to indicate unsuitability. If the saturation in the pulmonary arteries is higher than the aorta, an atrial redirection procedure, leaving the interventricular communication open, the so-called palliative atrial redirection, will improve streaming and improve systemic oxygenation. The concept of leaving the interventricular communication open is based on the premise that it will act as a route for decompression of the left ventricle if the pulmonary vascular resistance suddenly rises. Applying the same principles, a palliative arterial switch has been employed.⁸⁴ Given the

progressive nature of the pulmonary vascular disease, morbidity and mortality remain high.

Transposition with Coarctation of the Aorta or Interruption of the Aortic Arch

Obstruction of the aortic arch is rare when the ventricular septum is intact. It is more common in those with a ventricular septal defect, when it is often associated with anterior deviation of the outlet septum. Thus, the detection of hypoplasia, interruption, or coarctation of the aorta should alert the cardiologist to examine even more carefully the right ventricular outflow tract, the size of the right ventricle, and the tricuspid valve. If the right ventricle or tricuspid valve is small, a conventional repair may not be appropriate. It is generally accepted that a single-stage operation should be performed for repair of transposition associated with obstruction of the aortic arch. Although not the first to describe this as a single operation, Planché and coworkers were the first to demonstrate the superiority of this over a staged approach.^{85,86} The surgical technique for the aortic anastomosis does not require significant modification, as the Lecompte manoeuvre generally allows a direct repair of the coarctation with minimal tension on the anastomosis, though augmentation with a patch may occasionally be required.⁸⁷ A recent analysis of the arterial switch procedure in European centres did not demonstrate any additional risk of death in patients with an abnormality of the aortic arch.⁶⁴

Surgical Options in the Presence of Obstruction to the Left Ventricular Outflow Tract

Obstruction to left ventricular outflow, or pulmonary obstruction, is most commonly associated with a ventricular septal defect. Minor degrees of obstruction may be resected at the time of the arterial switch itself, and do not necessarily contraindicate this operation. Where the obstruction is severe or complex, it may be more appropriate to consider an alternative procedure. A number of approaches have been described:

Rastelli Procedure

The principle of this procedure is shown in Figure 38-37. It involves patching the interventricular communication so that the output of the left ventricle is directed to the aorta.

Figure 38-37 The cartoon shows the principles underscoring the Rastelli procedure used for anatomical correction of patients with transposition, a ventricular septal defect, and deviation of the muscular outlet septum (*left hand panel*). A patch is placed to create an intraventricular tunnel (*middle panel*), and an extra cardiac conduit is placed between the right ventricle (RV) and the pulmonary arteries (*right hand panel*). The pulmonary arteries are connected to the right ventricle using a homograft conduit.

Figure 38-38 The cartoon shows the end result of the Rastelli procedure, with a conduit from the morphologically right ventricle to the pulmonary arteries.

The pulmonary valve is oversewn, the pulmonary trunk divided or ligated, and continuity between the pulmonary artery and the right ventricle is established by a conduit (Fig. 38-38). The main drawback of this procedure is the high likelihood of the need for replacement of the conduit during later childhood.

Réparation à l'Étage Ventriculaire, or REV Procedure

This operation involves extensive resection of the outlet septum, and the use of a patch to baffle oxygenated blood from the left ventricle to the aorta.⁸⁸ The Lecompte manoeuvre is then performed, as for the arterial switch, and the pulmonary outflow tract is reconstructed by directly suturing the posterior rim of the pulmonary trunk to a right ventriculotomy (Fig. 38-39). Excellent rates of survival have been reported after the REV procedure, albeit with post-operative obstruction to the right ventricular outflow in one-quarter of patients, possibly related to the anterior location of the pulmonary arteries subsequent to the procedure.⁸⁹ To combat this problem, the technique

Figure 38-39 This cartoon shows the principles of the REV operation. As with the Rastelli operation, the procedure is employed for correction of patients with a ventricular septal defect and subpulmonary obstruction produced by posterior deviation of the outlet septum (*left hand panel*). The muscular outlet septum is resected and the aorta and the pulmonary trunk are divided (*middle panel*). The left ventricle (LV) is then patched to the aorta through the ventricular septal defect and, using the Lecompte manoeuvre to bring the pulmonary arteries anterior to the newly reconstructed aorta, the distal component of the divided pulmonary trunk (PT) is anastomosed to a right ventriculotomy, the anterior aspect of the pulmonary outflow being restored using a pericardial patch (*right hand panel*).

has been modified using a segment of aortic autograft to reconstruct the right ventricular outflow tract, keeping the pulmonary arteries in their anatomical position posterior to the aorta.⁹⁰

Nikaidoh Procedure, or Aortic Translocation

This procedure represents a very useful technique in patients with obstruction to left ventricular outflow, and offers a sound option to patients with anatomical variants that may render them unsuitable for the Rastelli or REV procedure.⁹¹ This includes patients with a small right ventricle, those with an inlet or restrictive ventricular septal defect, those with straddling or overriding of the atrioventricular valves, and those with a large coronary artery crossing the right ventricular outflow tract. The procedure (*Fig. 39-40*) involves harvesting the aortic root, along with the attached coronary arteries, from the right ventricle. The stenosed pulmonary valve is excised, and the outlet septum divided. The aortic root is then translocated posteriorly to lie over the left ventricle. The interventricular communication is closed, and the right ventricular outflow tract is reconstructed with pericardium. The pulmonary arteries, remaining posterior to the aorta, are connected to the right ventricle with a homograft. The Lecompte manoeuvre may be required, and sometimes the coronary arteries have to be detached and reimplanted to minimise rotational or longitudinal tension during translocation. The most intuitive advantage of the Nikaidoh over the REV, and particularly the Rastelli, operations, is that systemic outflow is not directed through an intraventricular baffle, and therefore the procedure carries a lower risk of obstruction developing later within the left ventricular outflow tract. Results from this procedure have been promising,⁹² although more extended follow-up is needed to assess any potential advantages over other procedures.

SURGICAL OUTCOMES

Atrial Redirection Procedures

The late outcome after atrial redirection is well understood, since the operation has been performed for nearly five decades. Long-term outcome has generally been very good,

with survival after 27 years of greater than 90%, nine-tenths of these not requiring reoperation.⁹³ When needed, the main indications for late surgery were obstruction of the venous baffles, failure of the systemic right ventricle, regurgitation of the tricuspid valve, and acquired obstruction to the left ventricular outflow tract (*Fig. 38-41*).⁹³ Obstruction to systemic venous return can be managed with transcatheter or surgical intervention. Balloon dilation tends to provide only temporary relief, whereas transcatheter stenting is more reliable and long-lasting.⁹⁴ An alternative option is reoperation, with the aim of either revising the baffle, or more complex surgery with conversion to the arterial switch. Others have reported the need for reoperation in only one-twentieth of almost 500 patients after a mean follow-up of 11.6 years for those undergoing the Mustard operation.⁹⁵

Late dysfunction of the systemic right ventricle is a frequent concern after an atrial redirection procedure, and is commonly associated with regurgitation of the systemic morphologically tricuspid valve. Medical treatment remains empirical, and is based on principles developed for the treatment of patients with left ventricular dysfunction in the setting of myocardial ischaemia. Thus, inhibitors of angiotensin-converting enzyme and β -blockers are commonly used, although data are lacking as to whether they improve either functional state or survival in patients after atrial redirection. The high incidence of ventricular dyssynchrony indicates that some patients may benefit from cardiac resynchronisation.⁹⁶ When failure of the morphologically right ventricle is more severe, the only options available may be cardiac transplantation or takedown of the atrial baffle and an arterial switch operation. The latter procedure is usually preceded by banding of the pulmonary trunk, in order to prepare the left ventricle, although patients with co-existing obstruction to the left ventricular outflow may be suitable for a single-stage procedure.

In a series of 39 patients who were entered into a programme for conversion to an anatomical repair at The Royal Children's Hospital, Melbourne, and The Cleveland Clinic Foundation, 4 underwent conversion as a single-stage

Figure 38-40 The cartoon shows the steps involved in the Nikaidoh procedure. This operation is also used for correction in patients with a ventricular septal defect and obstruction to outflow from the left ventricle into the pulmonary trunk. The upper left hand panel shows the original situation, with the dotted lines showing the incisions for division of the transposed arterial trunks, and the opening to the subaortic infundibulum. The middle panel of the upper row shows how the aortic root is liberated from the right ventricle, taking with it the coronary arteries, and an incision made through the outlet septum into the pulmonary root. The right hand panel of the upper row then shows how the anterior aspect of the pulmonary root is excised to widen the outflow from the left ventricle. The left hand panel of the lower row shows how the aortic root is translocated posteriorly and sutured into the outflow tract from the left ventricle, attaching the root to the ventricular septum with a patch so that the left ventricle ejects into the aorta. The aorta itself is then divided. The middle panel of the lower row shows how the separated pulmonary arteries are translocated between the components of the divided aorta, and the posterior aspect of the pulmonary trunk is attached to the superior aspect of the patch used to close the ventricular septal defect, the aorta having been reanastomosed behind the pulmonary trunk. The right hand panel of the lower row shows how the procedure is then completed by use of a patch to reconstruct the outflow tract from the right ventricle to the pulmonary arteries.

procedure, and 35 underwent preparatory banding of the pulmonary trunk.⁹⁷ Of those undergoing banding, three-fifths subsequently underwent anatomical repair, but the other two-fifths did not, as left ventricular training was not achieved. Of those that underwent anatomical repair, almost two-thirds either died or required transplantation. This series highlights the complex decision-making, and difficulty with predicting suitability for definitive surgery, in this high-risk group. In this cohort, banding was associated with an improvement in the severity of tricuspid regurgitation and functional state. This observation supports the concept that banding may be used as a palliative measure, even if conversion to an arterial switch cannot be performed.⁹⁸

Both atrial bradyarrhythmias and tachyarrhythmias are recognised complications of atrial redirection. Dysfunction of the sinus node is common, and is thought to be related to either damage to the sinus node or its blood supply at the time of surgery. Although the criteria for pacemaker insertion are equivocal, most would agree that if a patient is symptomatic, or if monitoring reveals long pauses, severe bradycardia, or tachyarrhythmia in the presence of bradycardia, then a pacemaker is justified, although implantation may be difficult because of the complex anatomy. Atrial tachyarrhythmias, including flutter, may precipitate deteriorations in ventricular function and may indicate an increased risk of sudden death. Antiarrhythmic therapies must be closely monitored because of the risk of

atrioventricular block, while radio-frequency ablation may be technically difficult because of the complexities of the anatomy, the presence of the baffle and atrial scarring.

Late Outcome after the Arterial Switch Procedure

General Health, Quality of Life, and Neurodevelopmental Outcome

The majority of children and adolescents who have undergone the arterial switch operation experience good overall health and quality of life that is not significantly different from their peers. Although they may undertake less exercise than controls,⁹⁹ their exercise capacity is usually excellent.¹⁰⁰ The intelligence quotient of most children late after the arterial switch operation is within normal limits. More detailed neurodevelopmental and neuropsychological assessment reveals that, while they achieve normal scores in many domains, they frequently perform below expectation in a number of aspects, including academic achievement, fine motor function, visual-spatial skills, and sustained attention.^{101,102} It will be important to determine not only which factors contribute to these deficits, but whether they can be alleviated by early neuropsychological interventions.

Fate of the Coronary Arteries

Translocation of the coronary arteries is a critical element of the arterial switch operation, and its success contributes to both early and late survival. In a review of late outcome in more than 1000 patients after the arterial switch operation, coronary arterial problems were reported in almost one-tenth, and these problems contributed to nearly one-third

Figure 38-41 Freedom from reoperation for failure of the systemic ventricle (A) and complications related to the baffle (B) for patients after a Senning operation. (From Horer J, Karl E, Theodoratou G, et al: Incidence and results of reoperations following the Senning operation: 27 years of follow-up in 314 patients at a single center. *Eur J Cardiothorac Surg* 2008;33:1061–1068.)

of late deaths.¹⁰³ There are a number of potential mechanisms for late problems after coronary arterial translocation, which include anatomical distortion, extrinsic compression, stretching, and intimal proliferation. There are a number of modalities for the diagnosis and investigation of coronary abnormalities. Currently, direct coronary angiography remains the gold standard investigation, although this can be technically challenging after reimplantation. A number of alternative, or complementary, investigational

modalities are now in use. These include myocardial perfusion techniques with technetium and thallium-201¹⁰⁴ and positive emission tomography.¹⁰⁵ Perfusion techniques have demonstrated that coronary arterial reserve may be decreased after the arterial switch, even in the absence of ischaemic symptoms. This concern is borne out by a study which confirmed a low, but significant, rate of coronary arterial occlusion or stenosis in nearly 8% of children at a median of 7 years after surgery. Importantly the

Figure 38-42 Survival free of reoperation for survivors of the arterial switch operation (A) and hazard functions for reoperation (B). Dotted lines indicate 70% CI. (Used with permission from Losay J, Touchot A, Serraf A, et al: Late outcome after arterial switch operation for transposition of the great arteries. *Circulation* 2001;104[Suppl I]:I-121–I-126.)

majority of these patients were asymptomatic.¹⁰⁶ More recently, coronary arterial lesions requiring intervention were identified in 5% of a cohort of 755 patients.¹⁰⁷

Innovative methods for detection of coronary arterial abnormalities have recently been reported. Multi-slice computed tomography¹⁰⁸ and magnetic resonance imaging may have a role in detecting ostial and proximal obstruction.¹⁰⁹ Intravascular ultrasound has also been used, and may specifically examine the lumen and intima of the coronary arteries.¹¹⁰ The exact implications of many of these findings are currently uncertain, but clearly are a potential concern, and reinforce the need for careful follow-up and regular reassessment.

Fate of the Neo-aortic Root and Valve

After the arterial switch operation, the native pulmonary valve must assume the function of the systemic arterial valve. In addition to the general concern that the pulmonary valve is not appropriately structured to fulfill this role, despite its semilunar arrangement, two of its three sinuses will have been incised at the time of original surgery in order to accommodate the coronary arterial buttons. These factors, combined with the recognised complication of dilation of the newly reconstructed aorta, place the patient at risk of neo-aortic incompetence. Such regurgitation across the neo-aortic valve was discovered in two-fifths of patients corrected with the arterial switch procedure after a mean follow-up of 20 months,¹¹¹ and after 10 years, only half are likely to be free of regurgitation.¹¹² Typically, regurgitation is associated with dilation of the ascending aorta, which may, in turn, reflect decreased distensibility and augmented reflection of waves within it, as well as abnormal angulation of the aortic arch after the arterial switch.^{113,114}

Pulmonary Arteries

Obstruction within the pulmonary outflow tract is the most frequent residual anatomical problem after the arterial switch operation, and is the most frequent indication for reoperation (Fig. 38-42). The obstruction can occur at multiple levels. Diffuse hypoplasia of the pulmonary trunk commonly results from inadequate mobilisation of the pulmonary arteries, leading to tension on, and flattening of, the reconstructed pulmonary channel. Circumferential narrowing at the anastomotic margins can cause discrete narrowing, while the right or left pulmonary arteries can themselves be stenotic. Such obstruction in the pulmonary outflow tract accounted for more than two-fifths of all reoperations reported in a recent series from Paris.¹⁰³ The majority of initial reoperations for pulmonary obstruction are required relatively early, within the first year after the arterial switch operation. This then commonly heralds the need for repeated reintervention.

RECOMMENDATIONS FOR LONG-TERM FOLLOW-UP

Guidelines from both North America and Europe suggest that, after surgery, patients should be followed indefinitely in a specialist centre dealing with adults having congenitally malformed hearts.^{115,116} The Canadian Adult Congenital Heart Network recommends regular detailed assessment, as outlined in Table 38-1.¹¹⁷

TABLE 38-1

PROTOCOLS DEVELOPED BY THE CANADIAN ADULT CONGENITAL HEART NETWORK FOR THE ASSESSMENT OF ADULTS WITH TRANSPOSED ARTERIAL TRUNKS

All patients should have at a minimum

- A thorough clinical assessment
- An electrocardiogram
- A chest radiograph
- Oximetry at rest and possibly with exercise

Patients who have had an atrial redirection procedure also require

- An echocardiogram to detect baffle obstruction or leak, to detect regurgitation of the atrioventricular valve, to assess the function of the systemic ventricle, and to detect subpulmonary obstruction
- A Holter monitor because of the high prevalence of sick sinus syndrome and atrial arrhythmias and possible ventricular arrhythmias in older patients

and may require

- A transoesophageal echocardiogram if there is inadequate visualisation of the intra-atrial baffle on the transthoracic study
- Radionuclide assessment of myocardial perfusion (if ischaemia is suspected), or of ventricular function
- Magnetic resonance imaging to evaluate the baffle for obstruction or leak and ventricular volumes, shapes, and function
- Cardiac catheterisation including coronary angiography if there are doubts about additional lesions, and if surgical reintervention is planned, or if adequate assessment of the haemodynamics is not obtained by non-invasive means
- Exercise testing to evaluate functional capacity, including heart rate and blood pressure measurement, and to assess whether arrhythmias may be provoked

Patients who have had an arterial switch operation also require

- An echocardiogram to assess obstruction to the right ventricular outflow tract, ventricular function, neo-aortic root dilation, and regurgitation of the aortic valve and the coronary arterial orifices
- Exercise testing for possible coronary ischaemia

and may require

- Holter monitoring if arrhythmia is suspected
- Nuclear assessment of myocardial perfusion periodically
- Coronary arteriography if ischaemia is documented on non-invasive testing
- Cardiac catheterisation if adequate assessment of the haemodynamics is not obtained by non-invasive means or additional lesions are suspected
- Magnetic resonance imaging to exclude obstruction of the right ventricular outflow tract

These articles provide an excellent reminder that, while the majority of children after the arterial switch operation have an excellent quality of life and outcome, a significant proportion demonstrate neurodevelopmental deficiencies. These articles will act as a stimulus for more detailed assessment of outcome and follow-up, as well as intervention studies.

Congenitally Corrected Transposition

WILLIAM J. BRAWN, TIMOTHY J.J. JONES, ROBERT H. ANDERSON, and DAVID J. BARRON

The essence of congenitally corrected transposition is the presence of discordant connections at both atrioventricular and ventriculo-arterial junctions. This segmental combination, like transposition itself (see Chapter 38), can be found in patients with either usual or mirror-imaged atrial arrangement (Fig. 39-1), but not in the presence of isomeric atrial appendages. Strictly speaking, congenitally correct transposition exists only when the ventriculo-arterial connections are also discordant. Discordant connections across the atrioventricular junctions, nonetheless, can also be found with double outlet from either ventricle, usually the morphologically right, with pulmonary or aortic atresia, and rarely with concordant ventriculo-arterial connections. These entities, therefore, are close cousins of the main malformation, and we will discuss their diagnosis and treatment in this chapter. The combination of discordant atrioventricular with concordant ventriculo-arterial connections, of course, produces the clinical picture of transposition, since the circulations are corrected only when there is double discordance. Even with double discordance, however, the purportedly corrected pattern of the circulation is usually perturbed by the associated anomalies, of which an interventricular communication, obstruction of the outflow tract from the morphologically left ventricle, and abnormalities of the morphologically tricuspid valve are sufficiently frequent to be considered part and parcel

of the malformation.^{1,2} The other complication occurring with sufficient frequency to be considered as almost part of the malformation is problems with the atrioventricular conduction axis.³ We will discuss all of these anatomical combinations, emphasising their clinical significance.

ANATOMY AND MORPHOGENESIS

Basic Morphology

As far as we are aware, the lesion was first described by the Baron Von Rokitsansky.⁴ It was with great prescience that he provided an exquisite illustration of the morphology as seen by the echocardiographer cutting the heart in the short axis of the ventricular mass (Fig. 39-2). When the atrial chambers are in their usual position, which is typically the situation, with only about one-tenth of all cases exhibiting mirror-imaged atrial arrangement, then by virtue of the discordant atrioventricular connections, the right-sided morphologically right atrium is connected to the right-sided morphologically left ventricle through a mitral valve, while the left atrium is joined to the left-sided morphologically right ventricle through a tricuspid valve. When the ventricular septum is intact, there is reversed off-setting of the septal attachments of the leaflets of the atrioventricular valves (Fig. 39-3). The morphologically left ventricle then gives rise to the pulmonary trunk, and almost always

Figure 39-1 Congenitally corrected transposition is the combination of discordant connections at both the atrioventricular and ventriculo-arterial junctions, and hence produces double discordance. It can exist in either usual (*left*) or mirror-imaged (*right*) arrangement, but not in patients with isomeric atrial appendages. Morph., morphologically; Pulm., pulmonary.

Figure 39-2 This illustration from the atlas of the Baron von Rokitsky⁴ shows the short axis of the ventricular mass viewed from the ventricular aspect in a specimen with congenitally corrected transposition with usual atrial arrangement. Note the fibrous continuity between the leaflets of the right-sided mitral (f) and pulmonary (g) valves, and the muscular infundibulum supporting the leaflets of the left-sided and anterior aortic valve (c).

Figure 39-4 A section taken slightly anterior and superior to the one shown in Figure 39-3 reveals the outflow tract from the right-sided morphologically left ventricle, which gives rise to the pulmonary trunk. Note the fibrous continuity between the leaflets of the pulmonary and mitral valves (*dotted red line*), and note how the outflow tract is wedged between the mitral valve and the septum. Morph., morphologically; Pulm., pulmonary.

Figure 39-3 This four-chamber section through a heart with congenitally corrected transposition and usual atrial arrangement shows the discordant atrioventricular connections. Note the reversed off-setting, albeit minimal, of the septal attachments of the atrioventricular valves (*arrows*) in this specimen with an intact ventricular septum. Morph., morphologically.

there is fibrous continuity between the leaflets of the pulmonary and mitral valves (Fig. 39-4). The wedging of the pulmonary valve between the septum and the mitral valve deviates the atrial septum away from the ventricular septum, this having crucial significance for the disposition of the atrioventricular conduction axis.⁴ The morphologically right ventricle, receiving the pulmonary venous return, empties into the aorta, which almost always in those with usual atrial arrangement is supported by a complete muscular infundibulum, the aortic valve typically being anterior and to the left relative to the pulmonary trunk (Figs. 39-5 and 39-6).

In a small proportion of hearts from patients with usually arranged atria, and with the segmental arrangement of congenitally corrected transposition, the aorta can be found in right-sided position, or directly anterior to the pulmonary trunk. Anterior and right-sided positioning of the aorta is the rule when congenitally corrected transposition is found in the mirror-imaged arrangement. L-transposition, therefore, is not the same thing as congenitally corrected transposition, the more so since left-sided aortas can be found in patients with regular transposition. Within the ventricles, the morphologically mitral valve is usually supported by paired papillary muscles located in infero-medial and supero-lateral positions. The supero-lateral papillary muscle is potentially vulnerable during surgical ventriculotomy, albeit that in most instances nowadays the surgeon approaches the ventricles either through an atrioventricular or arterial valve. In hearts with intact ventricular septal structures, the attachment of the morphologically tricuspid valve

Figure 39-5 A third section through the heart illustrated in Figures 39-3 and 39-4, taken still further anteriorly and superiorly, shows the origin of the aorta from the left-sided morphologically right ventricle. Note the complete muscular infundibulum supporting the leaflets of the aortic valve (red dotted line). Morph., morphologically.

Figure 39-6 In most instances when congenitally corrected transposition is found with usual atrial arrangement, the aorta, as in this heart, is positioned anteriorly and to the left relative to the pulmonary trunk. Morph., morphologically; Pulm., pulmonary.

to the extensive membranous septum creates an interventricular part, as in hearts with concordant atrioventricular connections, along with an atrioventricular portion. Unlike the normal situation, the atrioventricular part of the membranous septum separates the morphologically left atrium

from the morphologically left ventricle, the latter chamber being right-sided in the setting of usual atrial arrangement. There is also a prominent recess seen antero-superiorly within the morphologically left ventricle. This was a useful feature for recognition of the abnormality in the days when diagnosis depended on angiography.

In the past, it was frequently the practise to describe the ventricles as being inverted in the setting of usual atrial arrangement. In that they are not upside down, this is a less than accurate description of the ventricular arrangement. In terms of topology, nonetheless, the ventricular mass is the mirror image of the usual arrangement, exhibiting a left hand pattern when the atrial appendages are usually arranged, but showing right hand topology when the atrial chambers are mirror-imaged. Even with right hand topology, the ventricular mass is not the same as is seen in the normal heart, nor does the left hand topological arrangement show perfect mirror-imagery of the normal arrangement. This is largely due to the fact that the out-flow tracts are parallel to each other, rather than crossing, as in the normal situation. The ventricles, therefore, tend to be side by side, often with an added supero-inferior obliquity. It is also possible to find rotational abnormalities. It is marked abnormal rotation that produces the additional malformations known as criss-cross relationships,^{5,6} while excessive tilting produces supero-inferior ventricles.⁶ In addition to the ventricles occupying a side-by-side relationship, it is also frequent for the entire ventricular mass to be abnormally located within the thorax, and for the apex of the ventricular mass to point in unexpected directions. Finding the heart abnormally positioned, therefore, or an unusual orientation of the apex should always raise the suspicion of the congenitally corrected transposition.

As is always the case, the coronary arteries originate from the two aortic sinuses which are adjacent to the pulmonary trunk. It is usually the case that the right coronary artery arises from one of the adjacent sinuses, and the main stem of the left coronary artery from the other adjacent sinus, but sometimes both of the arteries arise from one or the other sinus, often with the arteries having a common stem.⁷ Their precise position relative to the heart will vary according to the precise position of the aortic root, but the specific arrangement is well described by taking note of their origin from either sinus #1 or #2 (Fig. 39-7). Origin of all three main coronary arteries from one or the other sinus is a frequent finding, often with the arteries having a common stem. The epicardial distribution of the arteries is reasonably constant, and is determined by the ventricular topology. Thus, in persons with atrial chambers in their expected position, the overall pattern is mirror-imaged relative to the arrangement seen in the normal heart. The right-sided coronary artery exhibits the pattern of a morphologically left coronary artery, with its short main stem dividing into anterior interventricular and circumflex branches (Fig. 39-8). The circumflex artery encircles the mitral orifice, which is right-sided when there is usual atrial arrangement. The position of the anterior interventricular artery is an excellent guide to the location of the ventricular septum. The left-sided coronary artery in the setting of usual atrial arrangement is a morphologically right coronary artery. It gives off infundibular and marginal branches while encircling the left-sided tricuspid orifice. In most instances, the inferior interventricular branch arises

Figure 39-7 As is the case for regular transposition, sinusal origin of the coronary arteries is best described by accounting for the origin of the arteries from either the right-handed sinus (#1) or the left-handed sinus (#2) as viewed by the observer standing in the non-adjacent aortic sinus and looking towards the pulmonary trunk. In most instances with usual atrial arrangement, as shown in the cartoon, it is the left-sided morphologically right coronary artery that arises from sinus #1, and the main stem of the morphologically left coronary artery from sinus #2.

Figure 39-8 The cartoon shows the usual arrangement of the coronary arteries in the setting of usual atrial arrangement, the arterial pattern dictated by the left hand ventricular topology almost always found in this setting. intervent., interventricular morph., morphologically.

Figure 39-9 When congenitally corrected transposition is found in the mirror-imaged variant, then the ventricular topology is almost always of right hand pattern. The epicardial arrangement of the coronary arteries, therefore, is anticipated for the normal heart. Ant., anterior.

from this artery. These relationships are all mirror-imaged when the atrial chambers themselves are mirror-imaged, since this arrangement is associated with right hand ventricular topology so as to produce congenitally corrected transposition. The epicardial pattern of the coronary arteries, therefore, resembles that expected for the normal heart (Fig. 39-9).

As we have already emphasised, because of the wedged position of the subpulmonary outflow tract in the morphologically left ventricle, there is gross malalignment between the atrial septum and the inlet part of the ventricular septum (Fig. 39-10). When the septal structures are intact, the septal aspect of the malalignment gap is filled by the extensive membranous septum. Not surprisingly, deficiency of this structure is common, producing a perimembranous ventricular septal defect. Because of the gross septal malalignment, it is impossible for the penetrating atrioventricular bundle to take its origin from the regular atrioventricular node, located at the apex of the triangle of Koch in the base of the atrial septum. Instead, the atrioventricular conduction axis originates from a second anomalously located atrioventricular node, located beneath the opening of the right atrial appendage at the lateral margin of the area of pulmonary-to-mitral valvar fibrous continuity (Fig. 39-11). The atrioventricular conduction axis, having penetrated through the fibrous trigone, comes to lie immediately underneath the pulmonary valvar leaflets. An extensive non-branching bundle then runs superficially underneath the right anterior facing leaflet of the pulmonary valve, descends for some distance down the anterior septal surface of the subpulmonary outflow tract,

Figure 39-10 In this heart with congenitally corrected transposition, the ventricular septum was intact. The image, taken from the apex of the right-sided morphologically (morph.) left ventricle, shows the malalignment gap (double-headed arrow) between the planes of the atrial septum (green line) and the ventricular septum (blue line). Because of the malalignment, the regular atrioventricular node at the apex of the triangle of Koch (squiggly symbol) is unable to make contact with the ventricular conduction axis (red cross-hatched area). Instead, the connecting bundle (red dotted line) runs antero-cephalad to the pulmonary valve, having taken origin from an anterior atrioventricular node (star).
